When renal incapacity is sufficiently pronounced it leads to a metabolic disaster to which the name of uræmia is given. That this disaster is due to an intoxication is generally agreed,—the mechanical explanations of Traube are no longer accepted,—but it is still doubtful what the poison is, or whether the various clinical manifestations which are grouped as uræmic are all due to the same poison, or indeed if they are all toxic in origin.

A damaged kidney not only allows materials to escape which it should retain, but retains those which it should excrete. In uræmia the retention of crystalloid substances in the blood is shown by the rise in its molecular concentration, as determined by lowering of the freezing-point.

In support of the retention theory, Bouchard sought to prove that the urine of a uræmic patient is less toxic for animals than that of a healthy person. But the methods at his disposal did not exclude the serious dis-

turbances set up by osmotic currents following the injection into the circulation of urine or of its solid ingredients. According to some observers, Bouchard's results can be explained as due to the poisonous effect of the potassium salts in concentrated normal urine.

In trying to identify some special constituent of the urine as responsible, attention was naturally first paid to urea as the most abundant. Reduction in urea excretion was easily demonstrated in uræmia. But the interpretation of this fact as bearing on uræmia falls to the ground now that it is known that the greater part of the urea comes directly from the protein of the food. A nephritic patient is usually given very little nitrogenous food, especially if uræmia be impending. Moreover, he frequently vomits and thus further reduces his intake. There is no doubt, however, as to the retention of urea in uræmia, both in the blood and in the cerebro-spinal fluid, and to precisely the same extent. According to Canti, patients with more than 0.2 per cent. of urea in the cerebro-spinal fluid are suffering from uræmia. The reading may rise to 0.7 per cent., and even if it is above 0.3 per cent. the case will be fatal. It should be pointed out that as the hypobromite method was used other nitrogenous bodies in the fluid would also react, so that it would be better to say that in uræmia the non-protein nitrogenous content of the cerebro-spinal fluid is increased. The urease method would give the amount of urea only, so that the difference between the results obtained by the two methods is an indication of the amount of amine bodies other than urea, to which the toxic effects are probably due. Urea is also found in the sweat and other secretions when it is eliminated with difficulty by the kidney.

Another reason against attributing uræmia simply to retention of urea is that urea is not toxic. Some years ago large amounts of urea were given for tuberculosis. There was no evidence that it was of benefit, but it certainly was harmless. Retention of uric acid, creatinin, the pigments and the salts of urine have each in turn been invoked to explain uræmia but without satisfactory evidence. In fact, when we compare the symptoms of complete obstructive suppression of urine, or urinæmia, with those of uræmia they are so different as to suggest a different origin. Ascoli says: "Severe urinæmia in man is chiefly manifested by bodily weakness and languor which often appear before any other symptoms, but generally lead to progressive mental weakness and exhaustion, often terminating with great suddenness. The greater part of the most prominent symptoms of uræmia are, however, lacking, especially the severe and acute mental disturbances, the sudden amaurosis, and the epileptic phenomena in general. Only in occasional cases do the symptoms resemble uræmia." The name of *latent uræmia* is sometimes given to this condition, but this is hardly suitable.

If, then, we abandon the view that uræmia is due to retention of one or more of the normal constituents we are thrown back on one of three explanations if uræmia is a toxic process. It might be due to: (1) Some precursor or derivative of urea. (2) Loss or alteration of an internal secretion of the kidneys. (3) Some product of abnormal metabolism.

The immediate precursor of urea is ammonium carbamate, from which it can be formed by simple dehydration. As the liver is the site of this change, hepatic insufficiency would lead to carbamate in the circulation, and this has been invoked to explain uræmia. In puerperal eclampsia

and acute yellow atrophy the toxic symptoms may be thus produced, as there is extensive destruction of liver cells. But in uræmia definite changes in the liver are unusual, and a relatively small amount of hepatic tissue is sufficient to convert enough ammonium carbamate into urea. Frerichs put forward the opposite view, that retention of urea in the body was followed by a reversal of this change, and he produced symptoms similar to those of uræmia by intravenous injections of ammonium carbamate. But the amount of ammonia in uræmic blood is not so great as in the blood of some diabetics in whom symptoms of uræmia are lacking.

Before uræmia can be referred to loss of the internal secretion of the kidney, the existence of such secretion must be proved. The evidence usually quoted is Rose Bradford's observation on the effect of partial nephrectomy in dogs. When the amount of kidney substance was largely reduced he found that the excretion of urea was increased. He suggested that the internal secretion of the kidney regulated nitrogenous katabolism, which in its absence went on unchecked. But Beddard and Bainbridge found that the increased output of urea occurred only as a terminal event when the animal was so ill that it was unable to take food and was starving. And it has long been known that after starvation for some time there is a rise of urea excretion—when the reserve of fat has been exhausted and the animal is reduced to living on its tissue protein alone, a condition under which life cannot be long supported.

Allied to this view is the hypothesis that the autolytic products of the kidney are the cause of uræmia. But in chronic interstitial nephritis the lesion is so slowly progressive that the amount of such products in the circulation at any one time must be infinitesimal, and yet the fatal issue may be due to uræmia.

We are therefore thrown back on the third hypothesis, that the defective excretion leads to the formation of abnormal products from perverted metabolism. It may be that there is one specific substance or a number of abnormal bodies responsible. The fact that the clinical manifestations are so various does not in itself prove the existence of different toxins. Alcohol can produce delirium tremens, peripheral neuritis, cirrhosis of the liver or cardiac enlargement under different conditions. But the demonstration by Lewis and Barcroft that there is a non-volatile acidæmia in uræmic dyspnœa is a strong point in favour of multiplicity of toxins, for this acidæmia will not produce the other manifestations of uræmia. Marriott and Howland attribute this acidæmia to the failure of the kidney to excrete acid phosphates. As to the nature of any other toxins we are still in doubt. Choline, a substitution product of ammonia formed from breaking down of the complicated fat of the nervous system, has been suggested, but this is unlikely, as it is a body of comparatively feeble toxicity and lowers blood-pressure, which usually remains high in this condition. A more promising suggestion is trimethylamine, another substituted ammonia. The so-called urinous smell in uræmia is due to this body, and the smell is absent in the urinæmia of simple suppression. Golla found that it was present in traces in normal urine and blood, but that it was increased tenfold in the blood of uræmic patients. In complete obstructive suppression, on the other hand, it was normal in amount. Experimentally trimethylamine has induced severe epileptiform convulsions.

We may conclude that at any rate some of the symptoms of uræmia are due to a toxæmia acting on the nervous system caused by the abnormal metabolic products resulting from inadequate excretion by a diseased kidney.

Symptoms.—A convenient clinical classification of the types of uræmia is: (1) *Cerebral* in the fulminating and acute cases; (2) *Respiratory* in the subacute cases; and (3) *Gastro-intestinal* in the chronic cases. The terms acute and chronic apply to the uræmia and not to the disease responsible for it. But each of these types is really nervous in origin. Usually the first type begins with severe headache. Drowsiness and twitchings of the face and hands follow. The twitchings may become aggravated into epileptiform convulsions, and the drowsiness may deepen into coma, ending in death. But several important departures from this course may occur. Sudden loss of vision, amaurosis, is not infrequent, although the fundi may not show the changes characteristic of albuminuric retinitis. Local palsies, hemiplegia or monoplegia, may come on spontaneously or after a convulsion, and are frequently due to small vascular lesions. Intense itching of the skin, tingling and numbness of the extremities, muscular cramps or insomnia may usher in the more serious symptoms. Sudden mania or delusional insanity may be the first and a very misleading symptom. Generally the cerebral type is rapidly fatal, but convulsions and amaurosis, though more striking, are less grave than the other symptoms. In the epidemic of war nephritis we saw seven instances of uræmic convulsions with complete recovery from the nephritis.

The commonest respiratory symptom is the paroxysmal dyspnoea, to which the name of uræmic asthma is given. It is associated with a fall in the CO_2 of the alveolar air from the normal 5 per cent. to 3 per cent. or lower. There is diminished alkalinity of the blood, from the presence of some non-volatile acid. Addison called attention to the hissing character of the respirations in this condition. In all types of uræmia there is a tendency to stomatitis, and this is perhaps particularly so in uræmic asthma. Rose Bradford says that the combination of dyspnoea of a hissing character in a drowsy patient with bleeding gums is very typical of the uræmic state. At first there may be no signs in the chest except the ordinary cardio-vascular signs of chronic nephritis, but as the attack proceeds there are usually abundant moist sounds from the onset of oedema of the lungs. The heart fails, the patient becomes steadily waterlogged, slipping down into the bed from the orthopnoic position as he becomes more and more drowsy. The fatal issue may not occur in this way, however, but from development of some of the more acute nervous symptoms.

Less common than this paroxysmal dyspnoea is Cheyne-Stokes respiration. The whole of the cerebral functions may then show a curious periodicity; thus the pulse quickens during the noisy breathing, the pupil dilates, the patient becomes more conscious and restless. As the apnoic pause succeeds the pulse slows down again, the pupil contracts and the patient becomes quieter or even comatose.

The gastro-intestinal symptoms are nausea, hiccough, vomiting and diarrhoea. The gastric part of these symptoms may be very chronic. Any practitioner who neglects systematic examination of the urine will sooner or later treat a case of uræmia as one of simple dyspepsia. Apart from

the urine, there is, however, one significant point: the dyspepsia may improve under treatment while the vomiting persists. In simple dyspepsia vomiting is never the last symptom to clear up. It is stated that this vomiting has no relation to meals, but this is far from being invariably true. Vomiting may occur only then, and so the mistake is made. In severer cases the vomiting may be quite uncontrollable, when the prognosis becomes correspondingly grave.

Attacks of diarrhœa are not uncommon in chronic nephritis and are not in themselves significant of uræmia. The amount of nitrogenous excretion occurring by the bowel, when urinary elimination is inadequate, irritates the intestine and leads to the so-called albuminuric ulceration. Another explanation of this condition is that hæmorrhages which occur here as elsewhere in chronic nephritis are the precursors of the ulceration. There may also be an intense catarrhal or even "diphtheritic" colitis. Here, therefore, there are local lesions sufficient to account for symptoms usually referred to uræmia, for such lesions are conspicuously absent at least in the asthmatic and gastric symptoms. It is accordingly inadvisable to call these symptoms uræmic, as is generally done. At any rate the term should be confined to those violent choleraic attacks which are out of all proportion to the local lesions. Both the vomiting and diarrhœa are sometimes regarded as an attempt at vicarious elimination of toxins. The fact that the vomit may contain a higher percentage of amines than the blood certainly suggests this.

In this way all the symptoms of uræmia could be regarded as due to toxins acting on the central nervous system, though sometimes manifesting themselves by local action on the medullary centres controlling respiration and vomiting. It is in accordance with what we find in other diseases, e.g. diphtheria, syphilis and lead poisoning, for a circulating toxin to exhibit this selective action on the nervous system. Evidence is, however, accumulating that vascular lesions in the brain play a larger part in the production of the uræmic syndrome than was previously thought, while terminal infections are frequently responsible for some of the symptoms.

Diagnosis.—This brief account of the symptoms of uræmia will indicate also some of the pitfalls besetting diagnosis. The greatest difficulty arises in distinguishing between hemiplegia due to uræmia and to cerebral hæmorrhage. In both there may be chronic interstitial nephritis with its urinary and cardio-vascular signs. In both the blood-pressure may be high and rising. But coma usually comes on sooner in hæmorrhage and becomes profound more rapidly. Ophthalmoscopic examination may be of great assistance, the existence of albuminuric retinitis pointing to uræmia. Some cases of cerebral tumour without localising signs, but with the classical symptoms of headache, vomiting and optic neuritis may be very difficult to distinguish from uræmia, if there is chronic nephritis as well,—a not very uncommon complication in syphilitic tumours of the brain. But such cases are more chronic in their course than uræmia. If the cerebral type of uræmia be accompanied by pyrexia, as it sometimes is, the question of meningitis must be considered. Lumbar puncture may then throw light on the case by the cytology, bacteriology and urea content of the fluid.

Cases of cardio-vascular disease in which the left side of the heart is failing may simulate uræmia. The urine is loaded with urates, twitchings do not occur, and the urea content of the cerebro-spinal fluid is low. Accord-

ing to Canti such cases occur after 45, while true uræmia is commoner before that age.

Other causes of coma must be taken into account,—alcohol, status epilepticus, trauma, opium, diabetes and the apoplectiform onset of general paralysis. The urinous smell of the breath may be a help. The fact that there is a fair quantity of urine may be misleading, for in chronic interstitial nephritis and contracted white kidney the daily excretion of water must be in excess of normal to maintain adequate elimination of solids. The presence of albumin is not sufficient, for any comatose person may have albuminuria. The presence of casts, other than hyaline, must also be established. For reasons already given, estimation of the urea in the urine is not likely to be of service, while an estimation of the blood urea is most helpful.

In the respiratory type the absence of adequate cardiac or pulmonary signs to account for the dyspnoea in a person not previously the subject of asthma will generally lead to a correct diagnosis, especially if the drowsiness and the condition of the mouth are duly considered. In the gastrointestinal type once attention is directed to the urine the condition will probably be recognised. The danger lies in the renal symptoms being overlooked because they may be trivial. Moreover, comparatively slight renal inadequacy may lead to toxic symptoms by the retention of some poison which would otherwise have been promptly eliminated. Thus salicylates, opium and mercury are badly excreted by the nephritic. Sometimes a patient who dies with symptoms resembling uræmia is found at the necropsy to have a very slight kidney lesion,—merely an adherent capsule and some diminution of the cortex. Then usually some other chronic intoxication such as pyorrhœa alveolaris will be found to have been at work as well.

Treatment.—This is unsatisfactory, as the underlying lesion is usually incurable and progressive. Only in acute nephritis can we expect to do more than stave off the fatal issue for a short time. When uræmia depends on an acute congestive nephritis the engorgement of the kidney may be relieved by the application of 4 dry cups to the loins. For the relief of vomiting, a minim of carbolic acid with 3 minims of dilute hydrocyanic acid and 10 minims of liquor adrenalin. hydrochlorid. in half an ounce of water every 3 or 4 hours sometimes affords relief. For the headache, a mixture of bromide and chloral hydrate is the best remedy, and doses of 20 to 80 grains of each may be required. But the main indication in the treatment of uræmia is the rapid elimination of the accumulating toxins in every possible way.

1. *Elimination by the bowels.*—Of all the routes available this is the simplest and one of the most effective. We should therefore never be in a hurry to check the diarrhœa which may be present, as it is nature's effort to get rid of toxins. According to von Noorden, 8 grammes of nitrogen can be excreted by the bowel in the day, while not more than 3 grammes can be excreted by the skin. Croton oil, elaterium and gamboge are open to the objection that they are very irritant to an already irritated intestine. A drachm of pulv. jalapæ co. or 5 grains of calomel, followed by $\frac{1}{2}$ an ounce of magnesium sulphate, should be tried. In milder cases of chronic uræmia a colocynth and hyoscyamus pill every other night may be sufficient. If not, 1 oz. of mist. sennæ co. should be given without delay.

2. *Elimination by the kidney.*—As uræmia is a manifestation of the failure of the kidney to do its work, but little response can be expected to diuretics. The action of diuretics is considered under chronic nephritis.

3. *Elimination by the skin.*—Not very much nitrogen can be got rid of in this way, and the method is open to the objection that the removal of so much fluid without a corresponding amount of organic solids concentrates the toxins in the circulation, while giving the kidney a more concentrated and therefore a more irritating urine to excrete. Diaphoresis, moreover, may be exhausting to the heart. One of the factors in the production of œdema in nephritis is the retention of salt, which raises the osmotic pressure of the tissues with a consequent retention of fluid which contains toxins. The elimination of salt by the skin may therefore be of service by making excretion by the kidney easier. In such cases we have found diaphoresis followed by diuresis, which is not the normal effect of sweating. The vapour bath or hot pack is more trying to the heart than the hot-air bath. None of these measures should be continued more than a quarter of an hour after sweating has begun, and a careful watch must be kept on the pulse; the procedure should be stopped at once if there are any signs of collapse, and stimulants should be at hand. If the treatment is having a good effect, sweating will begin at a lower temperature with successive baths. A nightly hot bath, containing 4 tablespoonsful of mustard, followed by wrapping in hot blankets until sweating has ceased is useful in some chronic cases, even when there is no œdema. Pilocarpine is profoundly depressing to the heart, and may lead to a drowsy patient being drowned in his own pulmonary and bronchial exudates. It is not often given now that the risks are more fully appreciated.

After diaphoresis the temperature may fall dangerously low in spite of hot bottles and blankets. The temporary improvement may sometimes, in our opinion, be too dearly purchased at the expense of the subsequent exhaustion.

4. *Elimination by bleeding.*—This is the most effective treatment. A spontaneous epistaxis has been noticed to avert a threatened attack of uræmia, and venesection is a rapid way of removing some of the toxins. It may be advantageously combined with the infusion of normal saline solution or of 1 per cent. of sodium acetate, which has been advocated as more easily excreted. With infusion a larger amount of blood can be safely abstracted and the toxins diluted. As the vascular tension is usually high the volume of fluid infused should be less than that of the blood removed. Thus 20 oz. of blood can be withdrawn and 10 oz. of fluid infused. In our experience this treatment is most applicable to cases of convulsions and amaurosis. Removal of cerebro-spinal fluid by lumbar puncture is a rational procedure, and is useful for the control of headache and of convulsions.

Since uræmic asthma is due to an acidæmia, a drachm of sodæ bicarb. should be given every 3 or 4 hours in this condition. Inhalations of oxygen have been recommended, but any benefit derived from them is probably due to their cardiac effect. Inhalations of chloroform may be useful in uræmic convulsions. Osler strongly recommends morphine, considering it indispensable for the restlessness and delirium. We have certainly known it to do good, but we are inclined to agree with Burney Yeo that, if it be used freely

for this purpose, the restlessness of uræmia may be relieved by the repose of death.

LARDACEOUS DISEASE

Synonyms.—Amyloid or Waxy Kidney.

Definition.—A pathological condition in which the blood vessels of the kidney, in more advanced cases the tunica of the tubules and the interstitial tissue also, are the seat of waxy degeneration.

Ætiology.—The affection is commoner in men than in women, and although occasionally seen in children it is more likely to occur in adolescence and earlier adult life, being uncommon after fifty years of age. It is usually due to chronic suppuration and syphilis. The influence of tuberculosis and diseases of the bones and joints is merely due to the obstinate suppuration which they excite. It is doubtful whether it ever occurs, apart from such conditions.

Pathology.—Amyloid material or lardacein is a product of protein degeneration, containing nitrogen, sulphur and chondroitin-sulphuric acid. In uncomplicated cases, the affected kidney has the appearance of a large white kidney with a smooth surface and a capsule that strips easily. The organ is firmer than it otherwise would be. On section, the cortex is thicker than normal and has a yellowish white appearance; the glomeruli may be visible as minute translucent spots. The pyramids are dark red, in contrast to the pale cortex. If a solution of iodine in potassium iodide is poured over the surface, some of the glomeruli stand out as mahogany-brown spots and the vasa recta as brown streaks. In histological preparations stained with methyl-violet, amyloid material takes a pink colour. The disease tends to appear first in the capillaries of some glomeruli, while others are normal, and its incidence is often partial within a single glomerulus. The afferent arterioles, vasa recta and capillary plexus are next affected; in more advanced cases there is amyloid degeneration of the tunica propria of the tubules with amyloid deposits in the interstitial tissue. In most cases there is an associated nephritis, interstitial rather than parenchymatous. The kidney lesion is generally the most striking part of a widespread lardaceous degeneration which also involves the liver, spleen and intestine; less commonly the blood vessels of the thyroid, suprarenals, pancreas, heart and brain may be affected as well. Occasionally only the kidney is implicated.

Symptoms.—The symptoms are not likely to occur unless chronic suppuration has existed for at least 3 months, and the onset is insidious.

The urine is copious, of low specific gravity (1003 to 1010). The amount of albumin is variable; when abundant there is probably coincident nephritis. The amount of urine and its specific gravity may also be affected by the presence and degree of coincident nephritis, and the state of the heart. Hyaline and granular casts are present in the urine; casts staining brown with iodine are not evidence of amyloid disease, and may occur in other diseases of the kidneys. True waxy casts are not found. In later stages there is œdema, with diminished excretion of urine. The blood-pressure is not raised, nor is the left ventricle hypertrophied, unless there is coexistent chronic nephritis.

Diagnosis.—The diagnosis is indicated by the nature of the urine. It is made (1) when there is a sufficient cause in the past history or present condition, namely, chronic suppuration or syphilis; (2) on the general condition of the patient, namely, a secondary anæmia, which may reach an extreme grade, with a pale or “alabaster” facies and cachexia; (3) on signs of lardaceous disease in other organs, such as enlargement of the liver or spleen and diarrhœa.

Course and Prognosis.—This depends on that of the primary cause. If the latter is unchecked, the disease is slowly progressive and death occurs from exhaustion due to the original disease, less often from uræmia. Where the original disease can be cured, recovery may occur. Complete recovery of the kidneys is less likely than is recovery of the liver, spleen and intestines.

Treatment.—The treatment is that of the original disease. In suppuration of the bones or joints, empyema, etc., it is surgical; but it must be recognised that in advanced cases surgical treatment may be too late, even though it is successful in eradicating the septic focus. In all cases fresh air and sunlight and a nourishing diet are essential. Iron, arsenic and cod-liver oil should be given. Cases of syphilitic origin should be treated with potassium iodide, in combination with iron and arsenic.

BACILLURIA

Synonym.—Bacteriuria.

Definition.—Bacilluria is a condition in which bacteria are present in the urine in such numbers as to render it hazy to the naked eye, without a corresponding reaction in any part of the urinary tract to their presence.

Ætiology.—Predisposing causes are constipation and obstruction to the outflow of urine, as in the bacilluria that may complicate pregnancy. The condition is found at all ages from infancy onwards, and is more common in females than in males. The infecting organism is *Bacillus coli* in the great majority of cases; less frequently *B. typhosus*, paratyphoid A and B, staphylococcus, streptococcus, and *B. proteus* are found.

Pathology.—There are three main paths of infection: (1) by the blood stream, (2) by lymphatics, and (3) by the urethra. In the first two of these a focus may be found, as in the bacilluria following typhoid fever or appendicitis, but sometimes post-mortem examination has shown a complete absence of any lesion. There is little reaction in the urinary tract to the infection; the mucous membrane of any part of it may show a mild degree of hyperæmia.

Symptoms.—The urine, immediately it is passed, has a hazy appearance; if it is poured into a test-tube, and the test-tube rotated, the urine has a characteristic “satiny” appearance or shimmer; it is not cleared by filtration. Its odour is often characteristic, being sometimes fishy in cases of *B. coli* infection and highly ammoniacal in *B. proteus* cases. Its reaction is acid, unless due to staphylococcal or *B. proteus* infection. It generally contains a trace of albumin, and often may contain a few white blood corpuscles and epithelial cells. A catheter specimen grown in broth, in dilutions of 1 c.c., $\frac{1}{10}$ c.c. and $\frac{1}{100}$ c.c. urine in 10 c.c. broth, gives a growth in all dilutions, and in *B. coli* infections there is generally a growth in more extreme dilutions.

There may be no other symptoms. On the other hand, there may be indefinite malaise, fever, gastro-intestinal disturbance, especially indigestion, constipation and abdominal pain; in other cases headaches, rigors and even meningism may occur. There may be local symptoms, such as enuresis in children and frequency of micturition in adults. When the symptoms point to inflammatory reaction in one part of the genito-urinary tract, such as pyelitis, cystitis, prostatitis, urethritis, or epididymitis, the condition is better diagnosed accordingly; even though bacilluria may be the primary condition.

Course and Prognosis.—The course varies greatly. The condition may be transient; more frequently it persists for weeks or months and shows a tendency to relapse. The prognosis should be guarded, in view of the possibility of complications and resistance to treatment, but in general it is good.

Treatment.—*Prophylaxis* is important in nurseries and children's hospitals, since there is evidence of spread of infection *via* the urethra, at any rate in females. Here it is a question of cleanliness. Having excluded as far as possible a focus of infection elsewhere, the main indications are rest, emptying of the bowel and flushing out of the kidney. In the initial stages at any rate, particularly if there are any general or local symptoms, the patient should rest in bed. The diet consists chiefly of carbohydrates, fruit and vegetables. Five pints or more fluid in the 24 hours are advisable, in the form of water, Malvern water, Vichy water, lemon drink, Imperial drink, barley water, weak tea and thin soups. Milk as such is unsuitable, though junket, butter-milk, whey and cream are food. Alcohol should be avoided. The bowels should be first emptied with castor oil and then kept open with salines or senna. Grey powder is also a useful laxative in such cases.

Urinary antiseptics are of value. The best plan appears to be to give enough potassium citrate in 20-grain doses every 4 hours in order to render the urine thoroughly alkaline for 10 days after the acute symptoms have subsided; then to give acid sodium phosphate in 30-grain doses three times a day, adding 10 grains of hexamine as soon as the urine again becomes acid. Sodium benzoate, 10 grains three times a day, may be useful, either by itself or with hexamine. It should be noted that hexamine is inert in an alkaline urine. Cystopurin (15 grains three times a day) or hexyl-resorcinol (2-grain capsules—one to three thrice daily) should be tried if hexamine proves ineffective or irritating. A change of antiseptic is sometimes advisable. Intestinal antiseptics are sometimes more efficacious, such as salol, 30 grains daily, or combined with boric acid, 15 grains daily. Boric acid is given in 5-grain keratin-coated capsules, to avoid gastric irritation. Sandal-wood oil is the most reliable antiseptic if the urine is alkaline from the first. In cases of delayed recovery, vaccines are a useful adjuvant; they do not replace other treatment, but are sometimes undoubtedly beneficial. *B. coli* vaccines are given in doses of 5 to 500 millions at 7 to 10 days' intervals, the dosage and interval depending on the particular case. It is important to bear in mind that bacilluria is often merely a complication of some other affection or disease of the urinary tract, such as renal calculus, tuberculosis of the kidney, pelvic abscess or neoplasm.

PYELITIS

Definition.—Pyelitis is inflammation of the renal pelvis. There is commonly some coincident inflammation of the renal parenchyma, but it is only when nephritis complicates the clinical picture that the condition is termed pyelo-nephritis.

Ætiology.—Most cases are due to a blood-borne infection of the renal pelvis, and it may be noted in this connection that it is a normal function of the kidney to excrete micro-organisms present in the blood stream; whether the renal parenchyma is, or is not, of necessity damaged in the process is a point on which there is not as yet exact information. The pelvis may also be involved by ascending infections—(a) via the lumen of the ureter when there is ureteral obstruction; it is probable that infection does not spread by this channel when the lumen is normally patent. (b) By way of the peri-ureteral lymphatics from local foci in lower parts of the urinary tract, such as the bladder, urethra, prostate, seminal vesicles and epididymis. Lastly, there is the possibility of direct spread of infection from the bowel, and by cross lymphatic channels from one kidney to the other. In those cases in which a pyelitis occurs secondary to appendicitis, cholecystitis, ulcerative colitis, etc., the spread of infection may be by the lymphatics or the blood stream.

In general, pyelitis is more common in females than in males. Its age incidence depends on the determining cause. Thus, it is common in female infants, as a result perhaps of urethral infection, to which they are more liable than male infants. It is not an uncommon complication of pregnancy, occurring especially in the fifth month of gestation. It is common in males at a later age, associated with enlarged prostate and cystitis.

Other ætiological factors which affect both sexes are stone in the kidney, tuberculosis of the kidney, the presence of any tumour pressing on the ureter and causing ureteral obstruction, such as pelvic tumours, cystitis from any cause, and urethral stricture.

Pathology.—The mucous membrane of the pelvis is swollen, oedematous and hyperæmic, and the submucous venules are engorged. Where there is obstruction, the pelvis is dilated and contains a slightly turbid or opalescent fluid. In these circumstances the ureter above the obstruction is dilated and tortuous and its walls are thickened. The kidney is swollen and pale, from cloudy swelling, and in severe cases there may be multiple small abscesses in the renal parenchyma.

Bacillus coli is by far the most common infecting micro-organism. Streptococci, staphylococci, gonococci and bacilli of the proteus and typhoid groups may be found. The infecting micro-organism is readily recovered from the urine.

Symptoms.—The clinical types of pyelitis differ greatly from one another, and the condition may be responsible for an acute fulminating illness or for a chronic malaise of indefinite nature.

LOCAL SYMPTOMS.—Pain is the most important, especially as a diagnostic indication in acute cases. It is of the nature of a dull ache in the loin or flank, at first slight and intermittent, later, or in other cases at once, constant

and sometimes intense. Occasionally it is like renal colic; there may be strangury. Increased frequency of micturition is a common symptom.

GENERAL SYMPTOMS.—In acute cases there may be sudden onset with rigors, vomiting, headache and the general constitutional disturbance of profound toxæmia. These cases may simulate septicæmia (in fact there may be septicæmia), appendicitis, or, when associated with abdominal distension, constipation and vomiting may even simulate intestinal obstruction. In other cases, with cerebral symptoms, meningitis may at first be difficult to exclude.

In subacute cases, without marked pain or rigors, there is general malaise, fever, anorexia, wasting and a secondary anæmia associated with some degree of polymorpho-nuclear leucocytosis (W.B.C. = 10 to 15,000).

In relapsing cases there are periods of exacerbation with acute symptoms, and intervening periods of fair health or general malaise. Fever is commonly present; in acute cases with rigors it may rise to 105° or 106° F. In general the temperature is irregular, remittent or intermittent, varying between 102° and 104° F. in acute cases, and 100° and 102° F. in subacute cases. The pulse is raised in proportion to the temperature, and there is a corresponding slight increase in the respiration rate. Of other general symptoms constipation or diarrhœa frequently precedes the disease, and constipation generally accompanies it. Toxæmia is often marked.

Deep tenderness on palpation of the renal region is the most important sign to determine. There is some degree of abdominal rigidity, and it may be possible to determine enlargement and tenderness of the kidney. The urine is characteristically turbid; it is at first febrile in character; later, chiefly as the result of treatment, it is pale and of diminished specific gravity. The turbidity is not entirely removed by filtration, and is of the character described under Bacilluria. Examination of the deposit (catheter specimen in women) shows pus cells and epithelial cells from the urinary tract. There may be hæmaturia. In all cases a rectal examination should be made to determine the condition of the prostate and seminal vesicles. Stones in the lower part of the ureter may be palpated.

Diagnosis.—In cases with fever and constitutional disturbance the differential diagnosis is from those diseases which come in their early phases under the category of indeterminate fever. The diagnosis is made on the examination of the urine. Pyonephrosis is diagnosed by the presence of a tumour. Calculus is recognised by its clinical features and by X-ray photograph. Perinephric abscess in its early stages is not accompanied by pyuria or frequency of micturition. Cystitis is generally afebrile; and it is accompanied by suprapubic discomfort and pain, particularly at the end of micturition. The diagnosis can be established by cystoscopy. Urethritis is recognised by local tenderness, urethral discharge and urethroscopy, and prostatitis by swelling and tenderness on rectal examination.

Prognosis.—The natural course in the majority of cases is to recovery in a few weeks. A longer interval generally elapses before the urine is free of bacteria. In a proportion of cases the complaint tends to become chronic, and among these are included cases that relapse, for in these the recovery has generally been incomplete. The disease may progress to pyelo-nephritis, suppurative nephritis, pyonephrosis or perinephric abscess. A fatal termination is rare, except when the condition complicates other disease,

such as paraplegia, or in elderly persons with obstruction to the outflow of urine.

Treatment.—Complete rest in bed is of first importance. Especial care must be taken to guard against chill. Otherwise the general treatment is that of a febrile illness. The bowels should be kept freely open with salines, after an initial dose of castor oil followed by an enema. The diet should be limited to fluids while there is fever, and in general is similar to that described under Bacilluria. If there is vomiting, fluid is given per rectum—half a pint 4-hourly. So long as there is toxæmia and fever, alkalis are given in sufficient dosage to render the urine alkaline; potassium citrate either alone, or combined with the bicarbonates of potassium and sodium, is given 2-hourly at first, then 3-hourly and 4-hourly so long as the urine is kept alkaline. After the temperature has been normal for some days and toxic symptoms are past, the medicinal treatment follows the lines advised under Bacilluria.

Chronic cases.—A short course of the treatment outlined for an acute case is advisable. Following this, every effort is to be made to build up the patient's resistance by living in fresh air, avoiding chill and over-fatigue, a generous and nourishing diet, and by so arranging the diet that the bowels are open regularly without taking purgatives other than a simple saline in the morning, or paraffin and agar. At the same time hexamine and acid sodium phosphate may be given, or an intestinal antiseptic, such as salol or izal. Vaccine treatment has proved efficacious in some cases, especially if given over long periods. F. Kidd has obtained good results by renal lavage with 5 per cent. colloid silver. In all cases a local focus of infection must be excluded by careful examination, since its removal is the first line in treatment, and its neglect is the cause of many chronic cases. In the rare fulminating cases, with suppurative nephritis, nephrectomy may save the patient's life.

PERINEPHRITIS AND PERINEPHRIC ABSCESS

1. Perinephritis without suppuration is really a part of some cases of chronic nephritis. Its clinical importance is not generally recognised, but it may be the sole cause of lumbar pain in that disease. The capsule of the kidney is thickened and adherent to the perirenal tissues, many of the adhesions being vascular.

2. Perinephritis proceeding to suppuration may be primary or secondary.

Ætiology and Pathology.—The primary form may follow injury, but more frequently it results from boils, carbuncles and tonsillitis, or complicates an acute specific fever. Soon after the Great War, cases were so common as to be described under the name of *epidemic perinephric suppuration*. The infecting organism is *Staphylococcus pyogenes*. J. Koch has shown experimentally that intravenous injection of staphylococci is followed by their excretion in the urine after an interval of 4 to 6 hours. In the process of excretion, according to Koch, they may give rise to multiple cortical abscesses, cylindrical medullary abscesses, or, passing along the cortical lymphatics, may gain access to the perinephric tissues and there cause abscess formation. In these circumstances perinephric abscess is an example of the

mildest form of staphylococcal pyæmia with single metastatic abscess formation. The secondary form may complicate suppuration in the neighbouring organs, such as the kidney, liver, gall-bladder or appendix. It may be secondary to caries of the spine. In other cases the infection may be carried by lymphatics from a focus in or around the bladder, rectum or female pelvic organs.

Such is the ordinary terminology, but it will be observed that the "primary" form is really due to infection from a distant focus through the blood stream, while the "secondary" is due to direct extension or infection through the lymphatics from some focus in the neighbourhood of the kidney.

Symptoms.—The general symptoms are fever of a hectic type, malaise, pallor and a toxic appearance; there may be rigors, sweats and vomiting. Seven to 14 days generally elapse before localising symptoms appear, such as abdominal pain, and slight fullness and resistance, with deep tenderness, in the affected loin. As the abscess forms, pain and tenderness increase, there is induration and, later, redness of the skin and œdema in the lumbar region. The tumour first tends to spread backwards, obliterating the normal hollow in the loin, and then as pus collects it may spread forwards, forming a tender tumour palpable from the front. In its relations to the colon it resembles a renal tumour, but does not move with respiration. There is resistance or rigidity of the abdominal wall on the affected side. There is an increasing polymorphonuclear leucocytosis. The urine is febrile in character, containing a trace of albumin and perhaps a few white blood corpuscles; it does not contain pus, unless the kidney itself is involved, but hæmaturia may occur.

Course.—When the condition is simply associated with chronic nephritis it has no separate significance. When it proceeds to suppuration the abscess may rupture into the peritoneum, colon or pleura, or on to the surface, unless the abscess is opened and drained.

Diagnosis.—Before localising signs appear the condition may be mistaken for typhoid fever, malaria or infective endocarditis. The blood examination is important for the purpose of excluding malarial parasites; leucocytosis is against typhoid fever, and when above 15,000 is in general against infective endocarditis. Absence of agglutination of micro-organisms of the typhoid group is further evidence.

When the tumour exists it has to be distinguished from a renal tumour or pyonephrosis. Renal and adrenal growths may be accompanied by fever, but do not usually give the general symptoms of suppuration; they tend to extend forwards rather than backwards, and induration of the tissues is absent. Pyonephrosis causes symptoms of suppuration and a tender swelling, but the tumour is circumscribed, moves with respiration, and does not cause any bulging in the lumbar region. Pyuria is usually present.

The diagnosis of caries of the spine, hip disease, and even of myositis as distinct from perinephritis may be difficult. Since perinephritis in itself induces lumbar rigidity and some degree of scoliosis, X-ray examination may be required to exclude caries of the spine. Hip-joint disease is excluded by absence of local tenderness and by the freedom of flexion and rotation of the thigh.

Treatment.—In the early stages, before there is evidence of suppuration, and when the chief symptom is lumbar pain, the treatment is that of a patient acutely ill with a general toxæmia. The bowels should be kept well open, and fomentations or poultices applied to the lumbar region. Aspirin may be given to relieve pain, and the local application of belladonna is of assistance. Early operation is important, and should be performed as soon as there are reasonable grounds for suspecting suppuration.

TUBERCULOSIS OF THE KIDNEYS

Small grey tubercles are frequently found scattered through the kidneys in persons who die of acute miliary tuberculosis; the kidney disease, however, scarcely affects the clinical aspect of the case, and this form of renal tuberculosis will not be considered here. Further, in patients who die of pulmonary tuberculosis it is not uncommon to find tuberculous foci in the kidneys post mortem, although there was no indication of their presence during life.

Clinical renal tuberculosis is either the fibro-caseating form of the disease, or it is tuberculous hydronephrosis. In either case, the tuberculous infection is generally primary in the kidney in so far as its clinical expression is concerned.

Ætiology.—The sexes are equally affected. The maximum age incidence is in the third and fourth decades; the disease is uncommon in the young and rare in the old. At an early stage the disease is unilateral. In the majority of cases the tubercle bacilli are carried to the kidney by the blood stream from a tuberculous focus, such as a caseating lymph gland. Recent experimental work has shown that bacteria do not ascend in the lumen of the ureter unless it is diseased, when the infection may spread by direct extension in its walls. Infection may also reach the kidney via the lymphatics in a proportion of cases. The path of infection is by way of the ureteric lymphatics, and it is probable that pelvic tuberculosis, for example, tuberculous prostatitis, may spread to the kidney by this route. There is also reason to think that tubercle bacilli from a diseased kidney may infect the opposite healthy kidney by the same lymphatic path, the bacilli first travelling in the urine and walls of the ureter from the diseased kidney and causing disease of the bladder, and then travelling from the bladder by way of the ureteric lymphatics to the sound kidney. On the other hand, there is a shorter path for infection from one kidney to another by the para-aortic lymphatic system. Since the disease in the other kidney takes the same anatomical form as it originally had in the kidney first affected, it is probable that, if the first is due to a blood-borne infection, so is the second. Vesical tuberculosis is, as a rule, secondary to infection elsewhere in the urogenital system, and the primary disease is commonly renal.

Pathology.—The initial lesion is in the cortex, or one of the pyramids, and it consists of one or more tubercles. The morbid process spreads by destruction of kidney tissue; there is caseation in the centre of the lesion, inflammatory reaction, with intense small-cell infiltration, giant-cell formation and more or less fibrosis at the periphery. The lesion also spreads by the deposition of tubercles at a distance; these are scattered through the

cortex, singly or in groups. Extension through the capsule is uncommon, but extension to the renal pelvis is frequent. Complete destruction of one or more pyramids may occur, or the disease may spread and involve one or more calyces or the entire pelvis. The resulting infiltration and cicatricial contraction may lead to hydro- or pyo-nephrosis. The disease tends to extend down the ureter, and the bladder is commonly infected at an early stage. Secondary infections may lead to metastatic abscesses in the kidneys and ultimately to destruction of the whole organ.

Symptoms.—Frequency of micturition is often the earliest symptom; it is first noticed by day and later at night. Urgency and painful micturition develop next. The urine may show no other abnormality than a trace of albumin at an early stage; characteristically it is pale and a little turbid from the presence of pus; it is acid in reaction, it may contain a few renal cells, and it is sterile on culture. By appropriate staining tubercle bacilli may be demonstrated in the centrifuged deposit. Hæmaturia may be the first symptom, or the disease may develop insidiously with lumbar pain. On examination, the kidney is sometimes enlarged, and it may be hard and irregular; it is often tender. Tenderness along the course of the ureter or thickening of the ureter, as determined by abdominal or rectal examination, is of great importance. The rest of the urino-genital system requires close examination; this should include cystoscopy and in some cases urethral catheterisation. X-ray examination of the abdomen may reveal calcified tuberculosis of the kidneys or lymph glands, and it may be required in the differential diagnosis from renal calculus. Finally, a careful review of the patient's history and present condition for evidence of a chronic bacterial toxæmia or of tuberculous infection elsewhere must be made.

Diagnosis.—The presence of tubercle bacilli in the urine, whether determined by microscopic examination of the stained deposit or by guinea-pig inoculation, is not absolute proof of renal tuberculosis, because the bacilli may be excreted by a healthy kidney or they may come from some other part of the urinary tract. Nevertheless, the demonstration of tubercle bacilli in the urine is of the first importance in a doubtful case, and the diagnosis may be established by cystoscopy. The cases which require most careful examination are those with an atypical onset, such as massive hæmaturia, and those in which there is a gross secondary infection when first seen. The possibility of renal tuberculosis must always be borne in mind in hydro- and pyo-nephrosis. The differential diagnosis from simple albuminuria and the several forms of Bright's disease is made on the presence of pyuria and the absence of signs and symptoms of chronic nephritis. Patients with pulmonary tuberculosis are perhaps more prone than others to chronic nephritis on account of the secondary infections which complicate their disease.

Course and Prognosis.—The onset is insidious and the course progressive. Natural recovery is hardly known, though occasionally an unsuspected caseous kidney may be found at autopsy on patients dying of other conditions. The disease runs an uncertain course, having a duration of a few years up to ten or even twelve years from the date of diagnosis. Death results from tuberculous toxæmia, secondary infection, or failure of renal function.

Treatment.—When the disease is unilateral the kidney should be

removed. Nephrectomy is rarely justified in bilateral disease. In any case the patient's health and resistance should be raised to the utmost by rest, fresh air and good food, on the general lines of treatment of tuberculosis of the lungs. Cautious tuberculin treatment may be indicated when the disease cannot be treated surgically.

RENAL CALCULI

Renal calculi may be composed of calcium oxalate, uric acid, urates, phosphates, cystin, or of a mixture of these.

Ætiology.—Two factors are required to form a renal calculus: crystals derived from the urine and some colloidal material to bind them together. Hence, as Benjamin Moore pointed out, the commonest nucleus of a stone is calcium oxalate, since oxaluria excites albuminuria and even hæmaturia, thus providing the necessary colloid. Infection of the urinary tract, such as pyelitis, will also act in this way by producing an inflammatory exudate. This is well seen in cystinuria, which will not lead to a calculus unless the urine becomes infected. Pure uric-acid stones may occur in quite young children, because in them a definite deposit of uric-acid crystals in the pyramids and pelvis of the kidney is almost a normal event. Milk is usually sufficiently diuretic to remove them; but if it is not, they irritate the epithelial lining of the pelvis, producing an outpouring of thick mucus which may cause the crystals to cohere. The former comparative frequency of uric-acid stones in the children of the poor in London was probably related to the scarcity of fresh vegetables in the diet, which leads to high acidity of the urine and consequent precipitation of uric-acid crystals. Such stones were also common in Norfolk, for some obscure reason. The factors leading to the deposits of various crystals in the urine have already been discussed (see Abnormalities of the Urinary Secretion). From this it will be noted that phosphatic stones will only occur in alkaline urine, so that they are generally accretions round a nucleus of some other material which has excited an ammoniacal decomposition.

Calculi may occur at any age, but are very rare in the old. They are commoner in males than in females. Those of sedentary habit are more liable to them. Alcohol and lead are said to predispose to renal calculi.

Pathology.—The pure oxalate stone is very hard, mulberry-shaped, stained by altered blood, and varies in size from that of a pea to that of a walnut. If it is encrusted with uric acid it becomes brown, and in form a coral-shaped mass, representing a cast of the renal pelvis and calices. Phosphatic stones are generally smooth and white. A cystin stone is hard, oval, light amber or greenish in colour, with a glistening surface. Other forms are rare. If the stone remains in the renal pelvis it may (1) by gradually increasing in size lead to the atrophy of the renal tissue; (2) by eroding the capsule of the kidney produce a fistula into the perinephric tissues, resulting in a perinephric abscess; (3) by obstructing the outflow of urine cause hydronephrosis or, more frequently, pyonephrosis. If it passes into the ureter it may become impacted, in this way again exciting hydronephrosis or pyonephrosis, or if it obstructs the ureter completely, may produce atrophy of the

kidney. If it causes ulceration of the ureter, this may be followed by a stenosis. If it passes into the bladder it is very likely to excite ammoniacal decomposition, and thus become encrusted with phosphates.

Symptoms.—A stone may remain latent in the kidney without causing any symptoms. More usually it causes pain, particularly on any jolting movement. This is occasionally referred to the opposite side, a point to be borne in mind when considering operation. A bout of pain may be accompanied by hæmaturia, and there may be albuminuria for some days afterwards. A small oxalate stone may produce more pain than a large uratic stone, because of its hardness and roughness. A large, branched uratic stone occasionally causes profuse hæmaturia without any pain. The results of renal calculi may be classified as (a) mechanical, (b) septic. Under the first heading come colic, hæmaturia, anuria, hydronephrosis; under the second, pyelitis, perinephric abscess, pyonephrosis. The frequency of septic complications can be understood when the importance of sepsis in the production of calculi is realised.

Renal colic is the most severe and distressing manifestation of calculus. It is particularly likely to be started by riding on a horse or in a train or omnibus, which causes the calculus to engage in the entrance to the ureter. Violent paroxysms of pain then occur, radiating along the course of the genito-crural nerve down into the groin and testis, which becomes retracted in the scrotum. The pain is also felt in the loin, and the muscles overlying the kidney become rigid. Vomiting and sweating are common. The patient is unable to keep still, and rolls about or gets on to his hand and knees, calling out with each paroxysm. He becomes pale and his pulse increases in frequency, and the temperature is apt to rise. During or after the attack there is usually some hæmaturia, and crystals may be found in the urine. The attack may last several hours and then end as abruptly as it began. Anuria is a serious symptom and implies that the ureter is completely blocked, and the other kidney is either diseased or its secretion reflexly inhibited. Occasionally both ureters may be blocked by calculi. Symptoms referred to the bladder, prostate or seminal vesicles do not occur until the stone reaches the bladder or the lower end of the ureter.

Diagnosis.—The occurrence of renal colic and hæmaturia suggests stone, but these symptoms may be produced by the passage of a blood clot from renal neoplasm or by acute pyelitis especially in a movable kidney. Ordinary examination of the abdomen reveals nothing beyond lumbar tenderness in uncomplicated cases. X-ray examination is of great value. Oxalate stones are the easiest to detect by that method, as even when small they throw a dense shadow. This is fortunate, since oxalate stones are the commonest. Pure uratic stones may not be detected unless they are large. Cystin stones throw very little shadow. Calcareous abdominal glands and phleboliths may be mistaken for calculi on X-ray examination. It may be necessary to fill the ureter with bromide through a ureteric catheter to prove whether the shadow seen is in the ureter. A skiagram of the pelvis should never be omitted, since a stone may have passed down to this region. Attacks of pain and hæmaturia with the presence of calcium oxalate crystals in the urine, but with a negative X-ray examination, are probably due to crises of oxaluria (see p. 1190). Appendicular colic may simulate renal colic, but the point of maximum tenderness is different.

Prognosis.—As long as there is no serious destruction of kidney substance or septic complication the outlook as to life is good, if treatment be adequate. Attacks of renal colic may occur from time to time, with great suffering, and even after stones have been removed by operation they may form again, though this is exceptional. Occasionally stones may be followed by a true chronic nephritis with its usual consequences.

Treatment.—The methods which should be employed when crystals likely to form stones are found in the urine have been described under urinary deposits. Disinfection of the urine should be carried out as described under bacilluria and pyelitis. It is well, however, not to render the urine alkaline when a stone is suspected, since this would lead to a deposit of phosphates upon it. A book of litmus papers should be given to the patient with instructions to place blue and red strips in the morning urine, which is likely to be the most acid. Enough citrate of potash should be given to render the urine amphoteric but not alkaline. Probably 20 grains at night will be sufficient for this purpose. The urine should be kept dilute by taking water freely. Mineral waters, such as Contrexéville and Evian, are helpful, the former particularly for uric acid, the latter for oxalates. Whey is also helpful when uric acid crystals are present. If a renal calculus is present, and this is confirmed by X-rays, removal by operation is indicated. The following points, however, are generally contra-indications for operation: (i) Large-branched stones, (ii) large bilateral stones, (iii) stones which are only the size of a pea or smaller, unless there is severe pain, extensive absorption of renal substance causing toxic symptoms, or obstruction to the outflow of urine. If the diagnosis is uncertain, or operation is refused or postponed or considered inadvisable because of the patient's general condition, the treatment appropriate to the deposit found in the urine should be continued. Violent exercise and jolting movements should be avoided. Small stones can often be got rid of by giving the patient 10 minims of tincture of belladonna with 10 grains of citrate of potash every 4 hours for a few days, and directing that 5 pints of water should be taken in the 24 hours. For the symptomatic relief of pain, aspirin in 10-grain doses, hot baths and antiphlogistine may be of service. Morphine should be avoided in the treatment of chronic renal pain, on account of the danger of establishing a habit.

For an attack of renal colic $\frac{1}{4}$ th to $\frac{1}{2}$ th of a grain of morphine tartrate together with $\frac{1}{160}$ th of a grain of atropine sulphate, should be given hypodermically. The anti-spasmodic effect of the atropine aids the onward passage of the stone, while the morphine relieves the pain. If morphine be given alone, the pain is apt to recur as soon as its anodyne effect passes off. Ten minims of tincture of belladonna should then be given in an ounce of water every 3 or 4 hours, with abundant fluids, as described above, until the pupils are dilated and the face rather flushed. Inhalations of chloroform may be necessary at the onset, until the drugs have had time to act. Hot applications to the loins or hot baths may help to relax spasm. Inversion of the patient has been advised, to attempt to disengage the stone from the ureter. After the paroxysm is over, the aid of X-rays should again be invoked to locate the stone if it has not been passed.

HYDRONEPHROSIS

Definition.—A condition in which the pelvis and calices of the kidney are distended by the accumulation of non-infected urine due to ureteral or urethral obstruction.

Ætiology.—**CONGENITAL.**—The condition may be congenital, due to an abnormality of the ureter or urethra; other congenital defects may be present. The ureteral stricture is commonly found at the exit of the ureter from the pelvis of the kidney, or near its entrance into the bladder. Other congenital causes are a faulty connection of the ureter to the pelvis of the kidney, or an aberrant renal artery. Hydronephrosis is sometimes found post mortem in infants and children without evidence of obstruction to the outflow of urine. In these cases the condition is presumed to be due to a neuro-muscular inco-ordination comparable to congenital hypertrophic stenosis of the pylorus.

ACQUIRED.—It is more common in females than in males, and the maximum age incidence in 74 cases collected by Herringham was between the third and sixth decade.

(a) *Bilateral* hydronephrosis results from stricture of the urethra, phimosis, enlarged prostate, obstruction within the bladder, or from a pelvic tumour; the last named is the commonest cause.

(b) *Unilateral* hydronephrosis is due to ureteral obstruction from—

1. **Blocking** of the outlet from the pelvis of the kidney by a stone, or by papillomatous growth, or by extension of a renal neoplasm or tuberculosis.
2. Stricture of the ureter following an acquired ureteritis.
3. Pressure on the ureter from without, particularly by tumours of the uterus and ovaries; peritoneal adhesions are an occasional cause.
4. **Torsion** of the ureter by displacement of a movable kidney.

Pathology.—The pelvis and calyces are dilated, and the renal parenchyma is flattened and atrophied. The whole organ in the early stages is not enlarged. In its later stages the pelvis may be greatly enlarged, and the renal parenchyma reduced to a thin-walled sac. When the kidney, as distinct from the pelvis, is chiefly affected, first the pyramids, and then the cortex, become hollowed out into large sacculi lined with a smooth white membrane, separated by septa of condensed renal tissue. These sacculi open into the pelvis, which may be relatively little dilated; they project as bosses on the surface of the organ. There is an associated chronic nephritis.

It is generally held that hydronephrosis results from intermittent obstruction. It has been produced experimentally, however, by ligature of the ureter causing complete obstruction. But complete obstruction is more usually followed by atrophy of the kidney.

Symptoms.—Many cases are latent, and give rise to no symptoms. The tumour may be discovered accidentally, or there may be complaint of pain in the flank or back. The onset is insidious.

The symptoms by which a hydronephrosis is indicated are the presence of a renal tumour and complaint of an aching pain in the flank or back, and sometimes polyuria or hæmaturia. In intermittent hydronephrosis, the tumour suddenly disappears with the passage of a large quantity of watery fluid; after an interval the tumour gradually reappears and finally empties

suddenly as before. This sequence may be repeated at intervals. Where true polyuria or hæmaturia occurs it is due to a coincident nephritis or pyelitis. There may be acute exacerbations of the chronic pain, with vomiting and collapse; such attacks may accompany emptying of the hydronephrotic sac.

Course.—When unilateral, hydronephrosis may never cause serious trouble, and intermittent cases may persist for years and finally disappear. In bilateral cases uræmia may supervene. Infection of the kidney is not uncommon, and may lead to acute pyonephrosis. The sac may discharge spontaneously through the ureter, and the fluid never reaccumulate. The sac may rupture into the peritoneum, or rarely through the diaphragm into the lung. Cases have occurred in which the ureter of the sound kidney has been blocked by a calculus.

Diagnosis.—The condition, especially when bilateral and unaccompanied by symptoms, is generally overlooked. In its most characteristic form, where the hydronephrosis is intermittent, the diagnosis is readily made. When the condition is apparent simply as a renal tumour the diagnosis from renal neoplasm (or retro-peritoneal glands in a child) is difficult. When the tumour is large it may be mistaken for an ovarian tumour. An examination with X-rays should be made, aided in difficult cases by filling the distended pelvis of the kidney with bromide through a ureteral catheter. In skilled hands this will definitely demonstrate the presence of hydronephrosis. Aspiration of the sac is occasionally practised for diagnostic purposes; but surgical exploration is a safer measure. Fluid from a hydronephrotic kidney is clear or slightly turbid, it contains albumin, and traces of urea and other urinary constituents; in the deposits are epithelial cells.

Prognosis.—This depends on the cause of the hydronephrosis and the condition of the opposite kidney.

Treatment.—The first indication is to remove the cause. Cases of intermittent hydronephrosis that do not cause serious symptoms should be treated on general lines. An abdominal belt to support a hydronephrotic mobile kidney may be of service.

In unilateral hydronephrosis causing serious symptoms, or of large size, nephrectomy is advisable. Since the state and function of the opposite kidney can be fairly accurately ascertained by pyelography and examination of a sample of urine obtained by ureteral catheterisation, nephrectomy is a less serious risk than it was before these exact methods of diagnosis were available.

In bilateral hydronephrosis the main indication is to remove the cause when possible, and to adopt every measure that may aid in preventing infection of the urinary tract.

PYONEPHROSIS

Definition.—Distention of the renal pelvis with pus, to an extent sufficient to cause a renal tumour.

Ætiology.—The affection is a sequela of pyelitis or hydronephrosis. There are two main types, namely, tuberculous and pyogenic pyonephrosis. The latter, which is the commoner, is most frequently due to an impacted calculus.

Symptoms.—The patient is wasted, toxic and febrile. Rigors are common. There is a renal tumour, which is tender on palpation, and moves to some extent with respiration. Pyuria is present, unless the ureter is completely obstructed.

Diagnosis.—The differential diagnosis from hydronephrosis is made from the presence of pyuria and of local and general symptoms of bacterial infection. Perinephric abscess gives signs of a more diffuse swelling, usually with œdema and redness of the surrounding skin, and does not move with respiration.

Treatment.—In bilateral cases the treatment is palliative. In unilateral cases nephrectomy is indicated, if tests show that the other kidney is adequate.

TUMOURS OF THE KIDNEY

BENIGN GROWTHS

These are of relatively slight importance.

ADENOMATA are the most common, occurring in the cortex or under the capsule. They may be single or multiple; multiple nodules commonly occur in sclerotic kidneys in old age. They seldom attain any size.

FIBROMATA are not uncommon as nodules, sometimes multiple, in the cortex or medulla. **LIPOMATA** and **ANGIOMATA** are rare.

MALIGNANT TUMOURS

SARCOMA.—Sarcoma occurs most commonly in infancy, in the first 3 years. On this account, according to Herringham, more malignant growths of the kidney are to be found in the first 5 years than in any 10 years during the rest of life. The tumours are congenital and are one of the most characteristic types of renal neoplasm.

Two forms are recognised—(a) *Sarcoma*, more often bilateral than carcinoma, may arise from the capsule or substance of the kidney. The structure is often alveolar and spindle- or round-celled.

(b) *Embryonal adeno-myosarcoma*.—These remarkable tumours contain glandular, fibrous, muscular and embryonal tissue. Such tumours lie within a distended renal capsule, and are solid and opaque. Large tumours tend to undergo cystic degeneration.

The prominent features of sarcomata are their frequent occurrence in infants, their rapid growth to a very large size, and fatal course. Metastases are exceptional; the liver is most frequently involved.

HYPERNEPHROMA.—These tumours arise from adrenal rests under the capsule of the kidney. They are single, large and well circumscribed. They are yellowish, fatty and vascular tumours, and are prone to hæmorrhage, necrosis and cystic degeneration. Typically there is a central fibrous core, surrounded by a more cellular cortical portion. They are more solid than adeno-carcinoma, and not lobulated as is the embryonal adeno-myosarcoma.

More recently the origin of these tumours has been disputed. If all tumours with distinct lumina are excluded from this category, and if it is recognised that the cells of adeno-carcinoma may show marked fatty change,

the number of true hypernephromata is considerably reduced. Since adrenal rests are relatively seldom found, it is probable that the number of hypernephromata has been overestimated in the past. It must be remembered that the kidney is also liable to invasion by a growth from the adrenal body.

ADENO-CARCINOMA.—It is difficult to determine the frequency of these tumours, on account of their confusion with hypernephromata. They occur as single, large, yellowish encapsuled tumours, or as small multiple growths in sclerotic kidneys. The tumours tend to spread along the renal veins into the inferior vena cava, and to the pelvis of the kidney and perinephric tissues. Metastatic deposits occur in the lymph glands along the aorta, lungs, liver, bones and brain. The suprarenal gland is frequently involved.

Symptoms.—1. Hæmaturia is the first symptom in more than 50 per cent. of the cases. It is much less frequent in children. The blood is fluid or clotted, and moulds of the pelvis or ureter may be passed. The hæmaturia is spontaneous, profuse and intermittent; it is little influenced by rest, nor is it provoked by exertion. It may be the only evidence of a neoplasm, and after lasting for a week or 14 days may cease, leaving no further evidence of the growth until at some later date a tumour is felt. The urine frequently contains albumin at intervals.

2. Pain is uncertain. It may be a dragging feeling, or a constant ache. The passage of clots may give rise to renal colic; otherwise the hæmaturia is not accompanied by pain.

3. The presence of a tumour is a most important sign. It is felt on deep palpation bimanually. It is first palpable below the ribs, outside the rectus muscle, as a solid swelling, with rounded borders, that moves with respiration. It may be possible to define its upper border. As the tumour increases, it tends to go forward. It may fill the hollow below the twelfth rib behind, but does not cause a swelling in the back. Large renal tumours cause asymmetry and bulging of the abdominal wall and marked displacement of neighbouring abdominal viscera. On the right side, the ascending colon lies in front, on the left the last part of the transverse colon and descending colon; the tumour is, therefore, resonant on percussion in front. When the tumour is highly vascular, pulsation is felt in it, and a systolic bruit may be heard over it. In later stages, the tumour is liable to become fixed by adhesions.

4. Progressive emaciation is generally late. It may be absent although the tumour is large.

5. Metastases are sometimes the first sign of a renal neoplasm, occurring in the lungs, bones or brain. Secondary deposits in the para-aortic lymph glands may cause obstruction to the inferior vena cava, or this may result from pressure of the tumour itself.

Diagnosis.—The diagnosis is made on the presence of hæmaturia, with a tumour. When hæmaturia occurs alone, cystoscopy will indicate the affected kidney; other causes of hæmaturia must be excluded by careful clinical, bacteriological and X-ray examination. When a tumour is the only sign an exploratory laparotomy is advised. The tumour requires to be distinguished from splenomegaly, hepatomegaly and Riedel's lobe. A renal tumour has not the definite edge characteristic of splenomegaly and enlargement of the liver. Enlargement of the liver is not often a source of difficulty. Splenic tumours are recognised by the fact that they tend to

occupy an oblique position in the abdominal wall, by the presence of a notch and of a sharp inner margin, free movement with respiration, and dullness to percussion. A Riedel's lobe is continuous with the liver, does not extend back into the loin, and is dull on percussion.

A differential diagnosis from retroperitoneal tumours, including those of the suprarenal, is not always possible, though the suprarenal growths may sometimes be recognised by certain characteristic features. Thus, there is the medullary sarcoma type described by Hutchison, generally occurring in children, characterised by metastases in the skull, ecchymotic swelling of the eyelids, papilloedema and severe anæmia, and the "infant Hercules" type of tumour of the adrenal cortex.

Prognosis.—The average duration is 4 to 5 years (Herringham), but it varies with the degree of malignancy. Recovery is rare.

Treatment.—Surgical treatment alone holds out a prospect of cure. Symptomatic treatment includes the use of drugs for the relief of pain and the control of hæmaturia; for the latter 20 to 60 minims of the tincture of hamamelis, or gr. $\frac{1}{4}$ of hydrastine hydrochloride, may be given every 4 hours for a few doses.

CYSTS OF THE KIDNEY

SOLITARY CYSTS

These may occur in an otherwise normal organ. They vary in size from very small cysts to tumours of considerable bulk. They result from dilatation of an obstructed tubule, and they may be congenital.

MULTIPLE CYSTS

Multiple cysts of small size are commonly met with in sclerotic kidneys. They result from chronic inflammatory changes that lead to obstruction of the tubules with subsequent dilatation. There are also rare cases of multiple cysts, of large size, whose ætiology and course are little known.

POLYCYSTIC DISEASE OF THE KIDNEYS

Definition.—Polycystic kidneys appear as a massive conglomeration of cysts, varying in size from a pin's head to a marble, separated by dense strands of fibrous tissue, in which little or no renal tissue is evident on naked-eye examination.

Ætiology and Pathology.—The commonest age incidence is between 40 and 50 years; they are relatively common in the decades preceding and following; they may occur in infancy and childhood, and of these a large proportion are in still-born infants. Those occurring in infants are congenital, and other congenital abnormalities may be present. Those occurring in adults may also be congenital; if that is the case, the condition must be progressive, for the lesion found on post-mortem examination is too severe to admit of its having had a long duration. It has been held that

polycystic kidneys are aberrant forms of chronic nephritis, with unusually large and numerous retention cysts. Intermediate forms, however, do not occur. It is alternatively suggested that the condition is a result of maldevelopment or a form of neoplasm.

The organs are enlarged in size, and weigh 20 to 30 ounces each, or even 3 to 4 lb. They have been compared to a bunch of grapes in appearance. The cysts project from the surface and form the mass of the organ. They are lined by a layer of flattened cells, and are filled with fluid. This fluid is clear or turbid, limpid or viscid, colourless or yellowish; it is sometimes blood-stained, giving it a red, purple or green colour. Urea has been found in the fluid, which may also contain fat globules, cellular debris, cholesterol and triple phosphate crystals. On microscopic examination more or less renal parenchyma is found in the septa between the cysts; the tubules are distorted, and exhibit varying degrees of atrophy, degeneration and dilatation, while the glomeruli show changes characteristic of chronic interstitial nephritis. The blood vessels of the kidney undergo sclerotic changes; there is increased fibrous connective tissue and small cell infiltration. In some cases cysts are also found in the liver, ovaries, broad ligament, uterus, pancreas and spleen; but they are rare in any other organ than the liver. More than one member of a family may be affected.

Symptoms.—The affection is nearly always bilateral. When the tumours develop to large size in the fœtus, difficulty in labour may result. In the adult there may be no symptoms, or any of the symptoms of chronic nephritis may develop and may terminate in uræmia, cerebral hæmorrhage or cardiac failure. General arterial disease, with raised blood-pressure and cardiac hypertrophy, is commonly present; on the other hand, the condition may reach an advanced stage and fatal termination without appreciable cardiac hypertrophy. In a third group the bilateral renal tumours are the most striking features, associated with general malaise, dull aching pain in the loins, and recurrent hæmaturia. The tumours are not tender, and present the ordinary signs of renal tumours (*q.v.*). The urine is of low specific gravity, and commonly contains a trace of albumin; there may be polyuria.

Course.—This usually follows that of chronic interstitial nephritis.

Diagnosis.—A condition of chronic interstitial nephritis with large palpable kidneys should suggest polycystic disease. Renal neoplasms other than sarcomata are nearly always unilateral. The absence of fever and pyuria excludes bilateral pyonephrosis.

Treatment.—The treatment is that of chronic nephritis. Operation is rarely indicated, since both kidneys are nearly always equally affected.

OTHER FORMS OF CYSTIC DISEASE

Echinococcus cysts may occur in the kidney, and the discharge of the daughter cysts has produced attacks of renal colic. *Cystic degeneration of renal neoplasms* is described elsewhere.

MOVABLE KIDNEY

The kidney is normally held in place by the perirenal fat, the renal vessels and the peritoneum stretched over it. But this does not prevent a certain

amount of respiratory excursion, as may be seen either by X-ray examination or in the operating theatre. The range of movement varies between 1 and 2 inches, and is more marked on the right than the left side. The term movable kidney should therefore only be applied to cases where there is an excessive respiratory descent, so that the upper as well as the lower pole can be felt, or where the kidney can be moved about by external manipulation. As the kidney slips downwards, the lower pole gradually passes towards the middle line, while the organ rotates slightly, causing the hilum to look somewhat forwards.

Ætiology.—Movable kidney is about seven times more common on the right than on the left side. On the right side, the liver is thought to exercise some downward pressure during its inspiratory descent—though this is doubtful, according to Christopher Addison. Moreover, the ascending colon and the hepatic flexure lie on the inner aspect of the right kidney, thus tending to drag it down when the bowel is loaded or dropped. On the left side, on the other hand, the strong costo-colic fold suspends the splenic flexure much more securely, while the descending colon lies to the outer side of the left kidney. Consequently this kidney is not nearly so exposed to downward pressure.

The condition is much commoner in women than in men. Of 667 cases collected by Kuttner, nearly 88 per cent. were in women. The principal reason for this difference is again an anatomical one. In men the kidney pouches are deep, narrow and rapidly diminish in breadth from above downwards, while in women they are much shallower and broader, and diminish only slightly in breadth from above downwards. This natural difference is accentuated in the spare long-waisted women with narrow loins, who are recognised as specially liable to floating kidney. The greater liability of women to chronic constipation further helps to induce dropping on the right side. Tight-lacing may formerly have been a contributory cause, but, before this can operate, it is necessary that the kidney should be lower than normal. Then, undoubtedly, tight-lacing can aggravate the condition.

Pathology.—Many reasons have been given for the occurrence of movable kidney; but few will stand investigation. The existence of a congenital mesonephron has been described in some cases. Wilson and Howell consider this a myth. They point out that, if the perirenal fat be absorbed, the kidney may become almost completely invested by peritoneum, or may slip into the mesocolon. The relaxation of the abdominal walls is frequently given as a cause; but the condition is quite frequent in nulliparæ. Wilson and Howell drew attention to the fact that if diminution in intra-abdominal tension played a large part in the production of a movable kidney, we should expect to find it occurring after the removal of large tumours from the abdomen. This would be the more likely since Nature provides no compensating mechanism in such cases as she does after parturition. But movable kidney is not a common sequel to such operations.

The wasting of fat around the kidney is also given as a cause, but, like tight-lacing, is probably only a contributory factor. Occasionally trauma would appear to be responsible. Glénard emphasised the frequency with which movable kidney is associated with a general visceroptosis. To-day, we may go further and assert that, except in rare traumatic cases, movable

kidney never occurs without visceroptosis, and that in women marked visceroptosis seldom occurs without rendering the kidneys unduly mobile. It is rare to see a case of movable kidney on the X-ray screen without finding definite gastropptosis. Naturally, if there is general visceroptosis, the kidney is its most obvious sign. It is a firm organ which can be readily grasped, while the other dropped viscera would elude palpation. As Landau says, "Pleased with his discovery, the physician may impute all subsequent symptoms to the movable kidney." Most of these are really due to visceroptosis.

The unduly mobile kidney may show certain changes. In the acute stage, the kidney may be large, gorged with blood and dull red, even purplish. In the chronic stage, the kidney is somewhat small and light, rather pale in colour and flabby. Local patches of chronic interstitial nephritis have been described by Hurry Fenwick; but these are certainly not common. A more serious sequel is the occasional occurrence of hydronephrosis produced by torsion of the ureter during the forward rotation of the organ or by its becoming kinked over the renal vessels. If hydronephrosis occurs, a subsequent infection may convert it into a pyonephrosis.

Symptoms.—There may be no symptoms at all and, if the movable kidney is only discovered in the course of routine examination, it is better not to tell the patient of its existence. It may be well, however, to inform a reliable relation, if such can be found, in order to protect one's self against a less discreet medical attendant subsequently revealing the fact to the patient. The commonest symptom is a constant dragging pain owing to traction on the renal plexus. This most frequently first declares itself between 25 and 35 years of age. A zone of hyperæsthesia corresponding to the distribution of the tenth thoracic segment may also be present. More serious symptoms directly due to movable kidney are Dietl's crises; but these are not common. The attacks are characterised by intense pain radiating down the ureter and through the back, shivering, nausea, vomiting, fever and collapse. The urine is scanty, and may contain blood. Sometimes the pelvis of the kidney may become distended, giving rise to an obvious increase in the size of the organ. This may pass off later, with abundant discharge of urine, showing that the crises are due to kinking and consequent partial obstruction of the ureter. If repeated, they may lead to hydronephrosis.

The other symptoms which have been attributed to floating kidney are really due to the associated visceroptosis. According to Bartels, dilatation of the stomach may occur from pressure of the dislocated kidney upon the duodenum. This is improbable and, where real dilatation of the stomach is found, it is usually atonic, or else there is kinking of the pylorus from marked gastropptosis. Gastropptosis, as already said, is the rule, and without an X-ray examination it is by no means easy to discriminate between a dilated and a dropped stomach. Constipation is very common, as it is in all cases of visceroptosis. Jaundice is certainly not due to pressure of the movable kidney on the bile-duct, as has been asserted, but is merely a complication of visceroptosis which permits of a more ready infection of the biliary passages. Neurasthenic and digestive symptoms, so commonly present, are the outcome of intestinal stasis from visceroptosis, and are not due directly to movable kidney. Naturally, if the patient is constantly in pain, she is likely to

develop nervous symptoms. But, apart from this, there is no reason to attribute far-reaching nervous consequences to movable kidney, yet, for some enthusiasts, hysteria in women, hypochondriasis in men, and even insanity, are common outcomes. There is little doubt that far too much stress has been laid upon this condition as a cause of manifold complaints.

To detect a movable kidney on the right side, the left hand should be placed under the loin while the patient is recumbent, though some authorities prefer a semi-recumbent posture. The patient should then be told to take a deep breath while the right hand is placed just under the edge of the liver in the nipple line. The kidney may then be felt to slip between the fingers. Usually, this does not cause the patient a definite pain, but a dull, sickening sensation. In the more advanced degree of the condition, the organ may be felt far from its normal position, even to the left of the middle line or nearly down to Poupart's ligament. In examining on the left side, the observer should stand on the patient's left, placing his right hand behind the loin and palpating in front with his left. It is a mistake to examine the left kidney for mobility by reaching over the patient.

A movable kidney usually feels larger than the normal excised organ. This is because of the surrounding investments through which it is felt.

Diagnosis.—Usually this is obvious, as the shape and mobility of the organ are so characteristic. Occasionally, a Riedel's lobe has been taken for movable kidney; but the continuity of the former with the liver should prevent this mistake being made. In the same way, a distended gall-bladder is continuous with the liver, and cannot be separated from it. Moreover, it is not nearly so movable, and curves characteristically towards the umbilicus. Carcinoma of the pylorus has offered difficulties in some cases: examination of the stools for occult blood, a test-meal and X-ray examination would clear up the diagnosis. Scybala near the flexures of the colon may be mistaken for floating kidney; but their indefinite shape and inelasticity generally help to distinguish them. Their disappearance after a series of enemata would settle the question. In one case a mesenteric cyst appeared closely to resemble a floating kidney.

Prognosis.—Apart from the development of hydronephrosis, movable kidney does not tend to shorten life in any way. It is doubtful whether a kidney once prolapsed can ever maintain the normal position unaided.

Treatment.—Some cases call for no local treatment, though the associated visceroptosis and neurasthenia will require attention. If pain is felt, the adoption, for a short time, of the knee-elbow position will help to replace the kidney and relieve the tension on the renal plexus. If pain is at all frequent, some form of abdominal support should be worn. Hurst has urged that the support should be designed to increase the general intra-abdominal pressure, and not to replace any one viscus. We are convinced that this is sound and that, in many cases, a "kidney belt" is worse than useless, while the addition of ingeniously placed pads only increases the discomfort. Curtis' support for visceroptosis is, in our opinion, much more satisfactory, while a specially designed corset for visceroptosis suits some cases better still. Whatever the form of the support it need only be worn while the patient is in the erect posture, and it is best fitted while she is recumbent, preferably with the pelvis raised on a pillow so as to aid the replacement of

the kidney. Often, when a support of this kind has been worn for a year or two, it is possible to give it up without recurrence of symptoms. Breathing exercises to develop the extension of the lower thorax, with exercises to improve the tone of the abdominal wall have in many cases proved more efficacious than a passive support. Operation should never be advised simply for pain, as it is rarely successful in relieving this symptom for more than a few weeks. On the other hand, if there is any evidence of hydronephrosis developing, the operation of nephropexy is advisable. But, even then, it may not be successful. In one case of Dietl's crises, followed by hydronephrosis, nephropexy had to be followed a year later by nephrectomy.

Treatment of Dietl's crises.—The patient must be put to bed and hot fomentations or antiphlogistine applied to the affected side. A hypodermic injection of a quarter to half a grain of morphine may be required if the pain is severe. Usually this is sufficient but, should the attack last more than a few hours, an attempt must be made, under an anæsthetic, to rectify the position of the kidney by manipulation. Naturally conditions are unfavourable for nephropexy during or immediately after a crisis, because of the congested state of the organ.

SECTION XVI

DISEASES OF THE JOINTS AND INFLAMMATORY DISEASES OF THE FIBROUS TISSUES AND MUSCLES

ARTHRITIS

INFLAMMATION of one or more joints occurs in many pathological conditions, and the following classification of the various forms is based upon their ætiology: (A) arthritis of known causation; and (B) varieties of arthritis in which the ætiology is at present somewhat obscure or indefinite.

(A) *Arthritis of known causation.*—1. Traumatic arthritis. 2. Specific infective arthritis, where the cause is definitely due to infection with the specific bacteria of known diseases, *e.g.*, gonococcal, dysenteric, pneumococcal, and tubercular arthritis; and the arthritis of known specific diseases, such as scarlet fever, Malta fever, dengue fever, typhoid and paratyphoid fever, syphilis, glanders, and acute septicæmia and pyæmia from blood infections with streptococci or other organisms. An infective arthritis may occur as the result of the blood infection in almost all the known infectious diseases, *e.g.* measles and mumps. Acute rheumatism or rheumatic fever will probably with advance of knowledge of its pathology come to be included in the "specific infective arthritis" group, for the evidence that its cause is due to infection by a specific organism is very strong. 3. Gout. 4. Arthritis following the injection of animal sera, *e.g.* anti-dysenteric, anti-diphtheritic, anti-tetanic, anti-meningococcus and anti-streptococcal sera. 5. Arthritis of neuropathic type due to disease of the nervous system, *e.g.* tabes dorsalis and syringomyelia. 6. Arthritis due to abnormal blood conditions, such as hæmophilia and purpura. 7. Arthritis associated with "Deficiency Diseases," *e.g.* scurvy and rickets.

(B) *Arthritis of obscure causation.*—In this group are included acute rheumatism or rheumatic fever, non-specific infective arthritis, intermittent hydrarthrosis, and hypertrophic osteo-arthropathy. In all probability most, if not all, of these forms of arthritis are due to an infective cause; and as our knowledge of their pathology extends, the types included in this group will become transferred to group (A) of arthritis of known causation.

(A) ARTHRITIS OF KNOWN CAUSATION

I. TRAUMATIC ARTHRITIS AND TRAUMATISM

Injury to a joint causes damage to its various structures, and hæmorrhagic or serous effusion results, with consequent inflammatory changes, such as pain and swelling. This is a surgical condition which is dealt with in works on surgery. Simple traumatic arthritis is non-progressive, and when the injured structures have healed under appropriate surgical treatment the arthritis should disappear. It must be remembered, however, that traumatism is frequently the cause of the development of a progressive arthritis of another type. Thus, in a tubercular subject the injury may be followed by the development of tubercular arthritis, and similarly an injury to a joint may start a progressive osteo-arthritis; this is commonly seen in osteo-arthritis of the hip-joint. In such cases there is a complex of ætiological factors present which predispose the patient to a particular form of arthritis and the injury to a joint determines the site of development.

II. SPECIFIC INFECTIVE ARTHRITIS

GONOCOCCAL ARTHRITIS OR GONORRHŒAL RHEUMATISM

This is one of the most serious complications of gonorrhœa. In a general blood infection with gonococci the fibrous tissues of the body are very liable to be affected; thus, the synovial membranes of the joints or tendon sheaths, the ligaments, fasciæ, aponeuroses, bursæ and the connective tissues generally may be involved.

Ætiology.—Gonococcal arthritis commonly occurs during an acute attack of gonorrhœa, but it may develop during the subsidence of an attack or in its chronic stages. Often strain or injury, exposure to cold, over-exertion and lack of care in the treatment of an attack of gonorrhœa lead to the development of arthritis. The complication occurs more frequently in men than in women.

Pathology.—The structures round the joint often show involvement, the tendon sheaths and bursæ being inflamed and swollen with effusion. The affected joints may be swollen, owing to exuded fluid. The effusion is usually turbid, and contains polynuclear leucocytes and synovial cells. Organisms may be found in the exudate of the joint or tendon sheath, and in such cases are usually found in the leucocytes present, but frequently the effusion is sterile. The fibrous tissues affected may contain gonococci. The plantar ligaments at their insertion into the heel may be the seat of a gonococcal infection, giving rise to the "painful heel of gonorrhœa," and organisms have been found in this situation. In an affected joint the organisms may disappear and the joint become normal. In other cases, however, fibrous adhesions may form in and around the joint, leading to fibrous ankylosis, and the involvement of the periosteum may cause a local osteitis with formation of osteophytes. Wasting of the muscles above and below an affected joint rapidly occurs if the arthritis is long continued, and deformities

of the feet may result from contraction or weakening of the ligaments. In some advanced cases the structures of the joints involved may undergo marked degenerative changes, such as are found in advanced osteo-arthritis, and permanent crippling results.

Symptoms.—The onset is often acute, with high temperature, general pains in joints and fibrous tissues, and the development of arthritis in one or more joints, usually the latter. The pyrexia may last for several weeks, and an examination of the joints shows often definite thickening and structural changes. The tendon sheaths and fibrous tissues may show signs of inflammation. Other complications may occur as the result of the gonorrhoeal infection. Thus, in the eye, gonococcal conjunctivitis, iritis, scleritis and keratitis may occur. The skin may show a condition known as "keratoderma blennorrhagica," in which red patches, about half an inch in diameter, occur, which become keratosed, forming hard dry yellowish elevations. They commonly occur on the soles of the feet. Endocarditis, pericarditis or pleurisy may develop during an attack.

Diagnosis.—Attention should always be paid to the existence of a gonorrhoeal urethritis and a special examination of the urogenital tract is advisable. Bacteriological examinations should be made of the urethral discharge, especially after prostatic massage, and also of the urine. The fluid from an affected joint should be bacteriologically examined for gonococci. While the illness resembles rheumatic fever in its acute symptoms, it differs in the fact that the arthritis when once developed in a joint lasts longer and does not quickly disappear under treatment with salicylates; the arthritis does not clear up in one joint and fly to another, as in acute rheumatism; and in gonorrhoeal arthritis the sterno-clavicular, temporo-maxillary, intervertebral and sacro-iliac joints are not uncommonly attacked, while these joints are rarely affected in rheumatic fever.

Treatment.—The most important part of the treatment is to cure the primary infection, and this should be treated by appropriate measures. Removal of the primary cause is usually followed in early cases by a rapid clearing up of the arthritis. Complete rest in bed and milk diet are necessary in the acute stage. The affected joints should be kept at rest, and local treatment, such as hot fomentations or iodine poultices, gives relief. Radiant heat is of value. Diathermy has given good results; also ionisation may be used with advantage after radiant heat treatment. Bier's method of treatment, by inducing hyperæmia of the affected joint, is sometimes beneficial. Drugs are of little use; but for relief of pain, aspirin phenacetin, or pyramidon may be useful.

Vaccine treatment is of value, and the best results are obtained from an autogenous vaccine. At first small doses of 1 to 2 millions, at intervals of about 4 days, should be given, and the dosage and the interval between them may be gradually increased. Serum treatment with anti-streptococcal or anti-gonococcal serum has been employed, but is inferior to vaccine treatment and is not to be recommended.

As the acute symptoms subside, care must be taken by careful passive movements, splints and bandaging, to prevent the formation of adhesions or contractures. In severe cases, where a large joint like the knee is involved, surgical treatment, such as tapping or incision and irrigation has given good results.

DYSENTERIC ARTHRITIS

Ætiology and Pathology.—Arthritis is a not uncommon complication of bacillary dysentery and occurs in from 1 to 2 per cent. of cases. It is very rare in amoebic dysentery, but a few cases have been observed late in the disease, and may have been due to secondary infection. Dysenteric arthritis occurs usually after the acute intestinal symptoms have subsided, and may develop in any period up to 3 months from the onset of the dysenteric attack. There is some evidence to show that a cessation of the diarrhoea, such as may occur after the administration of opium or other drugs, acts as a predisposing cause. Dysenteric arthritis is not due to the serum used in the treatment of dysentery, for it occurs in cases in which no serum has been given. Moreover, the arthritis following anti-dysenteric serum is simply a very transient synovial effusion occurring about 8 days after its administration, whereas dysenteric arthritis is a condition lasting some weeks, and if not carefully treated may lead to permanent joint changes. Bacteriological examination of the fluid from the affected joints is usually negative, but in a few cases dysentery bacilli, usually of the Shiga type, have been found. It must be remembered that one of the common sequelæ of dysentery is a post-dysenteric colitis due to a streptococcal or other intestinal infection. Cases of arthritis occurring in dysentery long after the specific organisms are present in the stools are probably due to these secondary infections, which are well known to be causes of infective arthritis.

Symptoms.—Usually more than one joint is affected. The knees are most frequently attacked, the ankles and elbows coming next in frequency; the finger, shoulder and wrist-joints are sometimes involved, and occasionally the temporo-maxillary and sterno-clavicular joints. Clinically the disease closely resembles gonorrhœal rheumatism, and in addition to the joints, the fibrous tissues, the ligaments and the tendon sheaths are frequently involved. Dysenteric arthritis usually causes a definite pyrexia, which lasts for a variable period. It may manifest itself as a synovial effusion (hydrarthrosis) into one or more joints, which gradually clears up, or there may be involvement of all the joint structures, with formation of adhesions and limitation of movement. In some cases severe pains occur in one or more joints (arthralgia), without the development of organic changes in the joint; this condition is due to a fibrositis involving the fibrous structure round the joint. Dysenteric arthritis, like gonorrhœal, is commonly complicated by a conjunctivitis affecting the lower and upper lids; this has been found to occur in about 50 per cent. of cases. It usually clears up in a few days, even without treatment. Iritis has been observed in a few cases.

Diagnosis.—The course of dysenteric arthritis is similar to that of the gonococcal variety, from which it is distinguished by the history or presence of a dysenteric infection and the negative evidence of a bacteriological examination for gonococci or history of recent gonorrhœa. It is distinguished from acute rheumatism by the absence of general sweating and cardiac complications.

Treatment.—The general and local treatment of the joints is on similar lines to that of gonorrhœal rheumatism. Specific treatment should be directed towards the intestinal infection. A bacteriological examination of

the stool, and of the material obtained from saline irrigations of the colon should be made, and if pathogenic organisms, such as dysentery bacilli, or abnormal streptococci, or other organisms likely to cause arthritis are found, a vaccine should be prepared and administered. Intestinal toxæmia may be treated with advantage by colon irrigation with normal saline on alternate days, and saline aperients, such as sodium or magnesium sulphate, should be administered by mouth, as well as intestinal antiseptics such as guaiacal carbonate or salol grs. x three times daily. Anti-dysenteric serum is not to be recommended for the treatment of dysenteric arthritis, as in cases where serum had been administered in the acute stage of the intestinal symptoms there would be serious danger of an anaphylactic collapse should further doses of anti-dysenteric serum be given when arthritis developed, for the interval between these events is sufficiently long to produce anaphylaxis.

PNEUMOCOCCAL ARTHRITIS

Ætiology.—Arthritis is a rare complication of a pneumococcal infection, and is due to the transference of organisms to the joint by the blood stream. It usually occurs during the acute stage of pneumonia, or within a fortnight of the crisis, but it has been observed to precede the lung involvement. In general pneumococcal septicæmia arthritis may occur during the course of the illness, even without involvement of the lungs.

Symptoms.—The joint symptoms are acute, with marked swelling and pain. One or more joints may be involved, but the knee is most commonly affected. The joint may become distended with pus, with much redness and œdema, and rapid disorganisation of the joint.

Treatment.—When the joint becomes purulent it should without delay be treated surgically by incision and drainage. In other cases the joint effusion is serous or sero-purulent, and the inflammation may subside with rest and local treatment similar to that for gonococcal arthritis. It is advisable in pneumococcal arthritis where much fluid is present to aspirate the joint, and the exudation should be bacteriologically examined. When the effusion is sero-purulent and improvement does not occur with rest and local treatment, incision and drainage of the joint should not be delayed. After the acute stage has subsided great care is necessary to prevent the formation of joint adhesions, and prolonged treatment will usually be required to enable the mobility of the joint to be restored.

TUBERCULAR ARTHRITIS

Tubercular arthritis usually occurs in young patients, and as an infection from a primary tubercular focus elsewhere in the body, and frequently signs of tuberculosis in other parts of the body are present. The possibility of an arthritis in a young subject being tubercular must always be borne in mind, and an X-ray examination is of great value in differentiating this type from other varieties. The subject is dealt with fully in surgical works, to which the reader is referred.

SCARLATINAL RHEUMATISM

Arthritis is a fairly common occurrence in the course of scarlet fever. It begins usually about the end of the first week, but may occur quite late in the disease, and some weeks after the temperature has become normal.

In the mild forms the affection is that of an arthralgia rather than an arthritis, severe joint pains without swelling occurring for a few days and then disappearing. In the more severe forms a synovitis with effusion occurs in the joints, and sometimes the peri-articular structures are involved. Scarlatinal rheumatism usually clears up completely with rest and general treatment. Some cases are benefited by salicylates. The resemblance to rheumatic fever is sometimes a close one, and it is possible that in these cases the two diseases may be occurring simultaneously. Since the specific pathogenic organisms of these diseases have not been definitely identified, it is impossible to dogmatise on their relationship.

In the pyæmic form of scarlet fever, suppuration of one or more joints as part of the general septicæmia infection may occur. These cases are usually fatal, and the arthritis should be treated surgically by incision and drainage.

MALTA FEVER

During the initial stage of the illness, pains in the joints (arthralgia) and muscles and fibrous tissues are common. During the relapses of fever which characterise this disease, effusions occur into one or more joints, associated with swelling and much pain. The arthritic effusions subside as the fever passes away, but may reappear with subsequent relapses. In addition to the joints, the fibrous tissues are often involved, giving rise to a painful fibrositis during the febrile periods. Organic joint changes do not usually result. The treatment consists of rest and local applications to the affected joints. Active treatment of the Malta fever infection is essential.

DENGUE FEVER (BREAK-BONE FEVER, DANDY FEVER)

Very severe pains in the joints and bones occur during this disease, and the joints often become red and swollen, owing to arthritic effusion. The arthritic symptoms clear up with subsidence of the fever, though joint pains may persist for some weeks.

TYPHOID AND PARATYPHOID FEVERS (ENTERIC FEVER)

In these diseases arthritis is a rare complication, and one or more joints may be involved. It may occur during the later weeks of the acute stage of the illness, but in very protracted cases a multiple suppurative arthritis may form part of a post-typhoid septicæmia and pyæmia.

Arthritis must be carefully distinguished from periostitis, which is a much commoner complication of enteric fever, and is usually suppurative in type, occurring either during the acute stage of the illness or after the general fever has subsided.

The arthritis of enteric fever is treated by rest and local applications. Should the effusion not subside, aspiration of the joint should be performed; and if pus be found, surgical treatment by incision and drainage is advisable.

SYPHILITIC ARTHRITIS

Acquired.—In the secondary form a joint effusion due to a synovitis may occur. It is associated with little or no pain, and usually clears up quickly with rest and anti-syphilitic treatment.

In the tertiary form the synovial membrane or capsule of the joint may be involved by gummatous thickening, and this, together with the associated effusion, will give rise to an irregular joint swelling, which may be of considerable size. Usually there is little or no pain, and there is fairly good mobility of the joint. In other cases a syphilitic osteitis may spread to a joint, which becomes involved in the inflammatory process, and an arthritic effusion results. A gummatous condition of the peri-articular structures, such as skin or fibrous tissue, may spread to the joint, causing a like result. The irregular swelling, and relative lack of pain, together with other evidence of syphilis and the blood tests, usually enable a diagnosis to be made; but this is more conclusively demonstrated by an X-ray examination, which shows the exact origin of the arthritis.

Congenital.—“Chronic effusion” due to “chronic syphilitic synovitis” occurs usually between the ages of 6 and 15 years, and both sexes are equally affected. It is a painless effusion, affecting nearly always both knees, though the swelling may be more marked in one than the other. The mobility of the joint is not impaired, and thickening of the joint structures does not occur. The malady is associated with interstitial keratitis in about 75 per cent. of cases. The course of the disease is prolonged, and there is a marked tendency to relapse after the effusion has disappeared.

Syphilitic epiphysitis usually occurs in infants under the age of 6 months, and is rarely confined to one joint. It is usually acute in onset, associated with pain and pyrexia, and resulting in a “pseudo-paralysis” of the affected limbs. Suppuration frequently occurs in the region of the epiphysis, owing to infection with pyogenic organisms (generally streptococci or staphylococci), and the inflammatory process may spread to the adjacent joint, causing an arthritis, which may be suppurative in type. The disease is well known, and the diagnosis is usually clear, since at this early age other causes of pseudo-paralysis are uncommon. Other stigmata of syphilis will probably be present, and a Wassermann test of the blood and an X-ray examination of the affected part may be made to confirm the diagnosis.

Surgical treatment will be required where suppuration is present.

All the above forms of syphilitic arthritis require in addition to rest and local measures a complete course of anti-syphilitic treatment, when the joint condition will make a rapid and permanent recovery.

GLANDERS

In the acute stage arthralgia is a common symptom, and in chronic cases, as a part of the pyæmic process of the disease, suppurative arthritis may occur, due to infection of the joint with the *Bacillus mallei*.

SEPTICÆMIC AND PYÆMIC ARTHRITIS

Blood infections of septicæmic or pyæmic type apart from those already mentioned are frequently accompanied by arthritis. Most commonly the

infecting organism is a streptococcus, but staphylococcal or other infections may be the cause. The arthritis is usually acute, and associated with much pain and swelling. It is commonly, but not always, suppurative in type, the presence of pus being indicated by marked redness and œdema round the joint. In cases of this type the joint effusion should always be bacteriologically examined after withdrawal by an exploring needle, and if pyogenic organisms are found, incision and drainage of the joint by surgical measures are not to be delayed.

ACUTE PERIOSTITIS

Acute periostitis is a common symptom of a streptococcal septicopyæmia in young persons, and frequently the epiphyseal neighbourhood is affected, so that the joint or bursa round it become involved by the acute inflammatory process in the proximity.

An examination will reveal the presence of marked tenderness and sometimes swelling, with perhaps redness and œdema over the affected bone, the site of specially marked tenderness being the bone and not the joint. In cases of this kind the suppurative periostitis is of a very acute nature, and will rapidly become an acute osteomyelitis if not dealt with without delay. The greatest care is necessary in order to differentiate this condition from acute rheumatism or other form of arthritis.

Treatment.—Immediate operation is necessary, and the infected periosteum should be freely opened and drained by appropriate surgical measures, the effusion being examined bacteriologically.

The arthritis associated with acute periostitis is commonly an acute synovitis of simple nature, caused by extension of the inflammation, but not the pyogenic organisms, to the joint, so that the synovial effusion is sterile. Surgical treatment of the periostitis is usually followed by rapid subsidence of the neighbouring arthritis. Should the arthritis not quickly clear up it is advisable to examine the joint effusion bacteriologically, and if this is infected with pyogenic organisms, surgical treatment of the joint should at once be adopted.

III. ARTHRITIS DUE TO GOUT (see p. 421)

IV. ARTHRITIS FOLLOWING THE INJECTION OF ANIMAL SERA

For arthritis following the injection of animal sera, see pp. 30, 39.

V. ARTHRITIS OF NEUROPATHIC TYPE

Lesions of the joints and bones may occur owing to the trophic changes associated with tabes dorsalis and syringomyelia. The knee- and hip-joints are most commonly affected, and in syringomyelia the joints of the upper extremity may be involved. In this condition there is marked swelling and disorganisation of the joint and an almost complete absence of pain. The joint may be distended with fluid, the capsule and ligaments round the joint becoming stretched and weakened. When the knee-joint is affected there is often very marked painless lateral movement.

Fractures of the shaft or portions of the head of a bone in proximity to the joint may occur, and irregular bony outgrowths (osteophytes), similar to those found in osteo-arthritis, may give rise to the irregular outline of the disorganised joint seen in advanced cases of this type. X-ray examination of the joint shows these changes together with marked organic alterations, such as absorption of cartilage and rarefaction of bone. This type of arthritis is easily recognised by the marked organic changes of painless character which have taken place and by the association of organic disease of the nervous system.

VI. ARTHRITIS DUE TO ABNORMAL BLOOD CONDITIONS

HÆMOPHILIA.—In this disease, hæmorrhage into joints and resulting arthritis are very common. The knees are most frequently involved, the ankle- and elbow-joints coming next in frequency, but any large or small joint may be affected. The hæmorrhage may be the result of an injury, but it is frequently apparently spontaneous, when probably some movement or jar acts as the exciting cause. The affected joint becomes distended with blood, and pain and slight rise of temperature may occur. The effused blood may be absorbed quickly without any definite impairment of joint function. In some cases a definite arthritis follows the hæmorrhage, the swollen joint becoming red and hot, and the synovial membranes inflamed. This condition may last some time, and occasionally osteophytic outgrowths may develop. The appearance of the joint may resemble that of tubercular arthritis, but it is really a condition of osteo-arthritis caused by the joint hæmorrhage. The third stage is that in which after absorption of the effusion, adhesions and marked organic changes occur, so that impaired movement and sometimes ankylosis result. An X-ray examination will now reveal changes similar to those of advanced osteo-arthritis. The joint affections of hæmophilia require rest and the general treatment recommended for the disease. Local treatment must be applied with great care, since fresh hæmorrhages are liable to occur into the joint affected.

PURPURA.—Joint affections occur in association with purpura, and these may be classified into the two groups:

(a) *Purpura simplex*, in which the eruption may be accompanied by joint pains and sometimes swelling from effusion, which quickly clear up with rest and appropriate general treatment (see p. 726).

(b) *Purpura rheumatica*, sometimes called Schönlein's disease. Joint pains are an early symptom, and swelling of the neighbouring joints occurs. The arthritis is caused by synovial effusion, and clears up without any permanent organic changes resulting.

VII. ARTHRITIS ASSOCIATED WITH "DEFICIENCY DISEASES"

Scurvy.—In infantile scurvy periosteal hæmorrhages are common, and sometimes hæmorrhagic effusions into joints occur. In the scurvy of adults, swelling of joints sometimes occurs, the affected joint being tense and distended, with a sero-sanguineous effusion. Other signs of scurvy will probably

be present, such as the characteristic gum changes, palatal hæmorrhages, hæmorrhage into muscles, purpuric skin eruption, or a hard brawny œdema of the legs and feet. Symptoms of this kind only occur after a dietary which for several months has been deficient in fresh vegetables, fruit and fresh meat.

The treatment of scorbutic arthritis consists in rest of the affected parts and dieting with foods of high anti-scorbutic value.

Rickets.—The bones, especially at their epiphyseal junctions, are involved in this condition, and stretching of the ligaments round the joints may occur. Arthritis does not occur primarily in rickets, and any arthritic manifestations are secondary to changes in the bones and ligaments.

(B) ARTHRITIS OF OBSCURE CAUSATION

ACUTE RHEUMATISM OR RHEUMATIC FEVER (see p. 292)

NON-SPECIFIC INFECTIVE ARTHRITIS

This includes the types of arthritis known as rheumatoid arthritis, arthritis deformans, osteo-arthritis, and chronic villous arthritis.

It is a disease of obscure causation, but probably due to an infection which is not uniform in origin. It is characterised by changes in the joint structures, which may involve the synovial membrane, the articular cartilages, the bones and the capsule, and in the peri-articular structures. Typical cases of the above types of arthritis differ in their morbid appearances, but great similarities are present in all, and a case belonging in its early stages to one type may in its later stages develop into another. Thus, a case of so-called rheumatoid arthritis, or of villous arthritis, may in the later stages of the disease develop the typical bone changes of osteo-arthritis.

The terms rheumatic gout and chronic articular rheumatism are also used to describe the above conditions; and since the terminology is so confusing, and also a source of misunderstanding, not only to the medical profession but to the public, it would appear desirable that the term non-specific infective arthritis be used to include them all.

Ætiology.—Much has been written about the causes of chronic rheumatic affections, but the majority of these can only be regarded as predisposing conditions and not as true causes.

Arthritis has a lower incidence rate amongst coloured than white races. Osler and McCrae, in their American statistics, have alluded to the relative immunity of the negro race, and this agrees with the writer's experience amongst large numbers of Indian troops in Mesopotamia. A family history of arthritis is commonly obtained from sufferers. It does not appear that the disease is hereditary, but it seems likely that there is inherited a tendency for the joints or fibrous tissues to be affected when a person is subjected to an exciting infective cause. Thus, a streptococcal infection may in one person give rise to chronic arthritis, while in another a severe anæmia or an infective endocarditis may result.

Sex has been regarded as a predisposing factor, the frequency in females being stated to be something like four times that in males. Age: while

infective arthritis is rare under 10 years, all ages are susceptible. Dr. G. F. Still has described a form of infective arthritis occurring in children of early years, 8 of his first 12 published cases occurring under the age of 3. From the age of 20 years infective arthritis has a relatively large incidence for all ages, and the small numbers given for advanced ages are to be explained by the small population from which they are drawn at these periods of life.

Mental strain and debility, by lowering the general resistance, predispose, if the exciting infective cause is present. Trauma and physical strain may cause an arthritis or fibrositis, but this condition will not be progressive unless some infective cause is present at the time of the injury. It is well known that an injury is often the starting-point of a progressive arthritis, and this is commonly the case in osteo-arthritis of the hip-joint. Exposure to cold, wet and damp, and living in houses without proper damp-proof courses, particularly in districts where the subsoil is damp and the subsoil water high, all act as predisposing causes. Pregnancy and parturition are sometimes followed by a non-specific infective arthritis. It is well known that an existing infection in the body—for example, pulmonary tuberculosis—often undergoes a rapid development as the result of pregnancy, and in a similar way a latent streptococcal or other infection may be set up and cause a non-specific infective arthritis. This is the probable explanation of the ætiological bearing of pregnancy on arthritis. Disease of the nervous system is not associated with infective arthritis or the various forms of fibrositis. The changes seen in the so-called Charcot's joints of tabes or syringomyelia are due to trophic changes from spinal-cord disease, which, together, often with trauma, lead to severe organic changes in the affected joints. For many years dietetic errors in food and drink held sway as supposed exciting causes. Excess of protein in the dietary, drinking alcoholic beverages, such as certain wines and beer, and the taking of acid fruits, were all thought to play an important part, but the modern view is that metabolic factors have little or no influence in the causation of infective arthritis.

The conclusion which forces itself upon one from a close study of cases of non-specific infective arthritis is that the real exciting cause is an infection, the continued absorption of toxic substances giving rise to the inflammatory changes in the joints and fibrous tissues. It has been my experience that in the great majority of these cases a streptococcal infection from some focus in the body is the exciting cause, though in some cases another organism may cause similar effects—for example, the *Bacillus coli communis* group of bacteria. Arthritis from specific infections is well known, and the various examples of this type have been already described.

Pathology.—The disease, when not associated with a general specific infection, is, it is believed, in all cases due to some localised infection of the body, generally of a streptococcal nature. The organism causing the infection cannot usually be obtained from the affected joint or tissues, and in all probability the pathological changes are due to the toxins absorbed. A very large number of bacteriological examinations of the affected joints have been made by numerous skilled observers, but no specific organism has been found, and generally the results have been negative. In a few cases a streptococcus or a bacillus has been found in the affected joints, but proof has generally been wanting that this organism was the primary cause of the

arthritis in question. Poynton and Paine isolated from one case of infective arthritis a streptococcus which caused similar lesions in rabbits. It appears probable that in the majority of cases the affected joints and tissues are devoid of living bacteria. This is not surprising, since the causal infection is often of a relatively low type of virulence, and often far distant from the affected joints. An analogous example is to be found in the pleurisy, with sterile effusion, frequently present over a subphrenic abscess containing pathogenic organisms.

The cause of an infective arthritis should always be sought for. A careful clinical examination of all the organs should be made, but frequently no apparent cause is visible. The commonest cause of infection is to be found in connection with the teeth sockets. Dr. Beddard, in October 1918,¹ placed 90 per cent. of cases of so-called rheumatoid arthritis in this category, and my personal experience agrees with this view. Very commonly the teeth and gums appear healthy, and give rise to little suspicion, even after a close examination; but sometimes there may be visual evidence of caries and gingivitis, and on pressure pus may be expressed from the space between the gum and the teeth. It cannot be too clearly realised that the infection which is most likely to be the cause of an arthritis and allied conditions is often deeply seated near the apex of the tooth and gives rise to no symptoms whatever, and pain, swelling and tenderness may be entirely absent. The only certain method of examination of the tooth sockets is by means of X-rays; this should be done in every case, photographs of the individual teeth being taken. Usually there is definite evidence of osteitis, with rarefaction or destruction of the alveolus, and the most striking evidence of all is the indication of an apical abscess or granuloma shown in the print by the clear white space around the apex of the tooth. This space is invariably filled with pus or granulations heavily infected with pathogenic streptococci, and must serve as a constant supply of virulent toxins, if not of bacteria, into the blood stream. On very many occasions this condition has been associated with infective arthritis and the various forms of fibrositis. Where arthritis is present and a dental origin is discovered, almost always streptococci showing similar bacteriological characters are found in profusion in the fæces, and in cases of progressive arthritis after all the teeth have been removed, there is usually found bacteriological evidence of a marked streptococcal intestinal infection. The streptococci causing arthritis usually belong to the "viridans" group, and sometimes hæmolytic streptococci accompany these. Intestinal infections may, apart from dental infections, give rise to arthritis, but in such cases there is generally evidence of attacks of entero-colitis with diarrhœa and loose stools containing mucus. The causation of dysenteric arthritis by bacillary dysentery has been mentioned. In this country intestinal infections are uncommon primary infective causes of arthritis.

A septic condition of the tonsils and adenoids, of streptococcal type, may give rise to arthritis and allied conditions. A careful examination of the tonsils should always be made, and if unhealthy looking, pressure should be applied to see if pus can be expressed. The maxillary antra and nasal sinuses should be carefully examined by illumination and other methods for a possible source of infection. The uterus and genital organs also should be examined. In my experience infections from these organs, apart from

¹ *Transactions Medical Society of London.*

gonorrhoea, are very rarely the cause of arthritis and allied conditions. Any focus of suppuration may act as the cause of a general infective arthritis; thus, infected wounds or a suppurating joint may give rise to a non-suppurating general arthritis (McCrae).

The morbid changes in the joints in this condition have been described by Strangeways and others. Briefly, they consist of swelling and hyperæmia of the synovial membrane, and in the villous form this may attain a high degree of proliferation. The fluid in the joint is slightly turbid from the presence of small fibrous deposits, and usually contains lymphocytes and a few polynuclear cells. Later, the capsule of the joint becomes involved, and inflammatory processes are set up which may go on to thickening and contraction. The cartilage of the joint becomes affected, the surface being roughened and irregular with small elevations, and may become the seat of a fibrous tissue degeneration, with blood vessels spreading through it. The cartilage becomes thinned and may almost entirely disappear.

Atrophic changes occur in the bones, and the density becomes diminished. At the apposed surfaces absorption occurs in advanced cases, and at the periphery osteophytic outgrowths of softish bone, so that a mushroom appearance may be produced. In the synovial fringes, thickened fibrous nodules, partly calcified, may develop, and these sometimes become dislodged, forming loose bodies in the joint. In extreme cases a fibrous or partly bony ankylosis may result. The changes to be seen in X-ray photographs are rarefaction of the involved bone and a fuzziness of the articular surfaces, as if a very thin layer of fine cotton-wool covered them, due to the irregularity of the surface of the bone in consequence of the changes described. The clear space between the opposed bones is diminished, as a result of cartilage absorption. Loose osteophytes may be seen in some cases. Lipping of the bones or slight outgrowths may be visible.

Symptoms.—It cannot be too strongly insisted upon that the most careful examination must be made to determine exactly what structures are affected. Each joint should be carefully examined for evidence of swelling, pain on movement, and crepitation, creaking or grating. A careful examination should also be made of the bursæ around the joints of the tendons and of the tendon sheaths. The freedom of movement in all directions of each joint should be carefully tested and any limitation noticed.

Some cases begin with an acute onset of pyrexia and general symptoms in addition to the local. Such cases of acute infective arthritis often completely clear up with rest and treatment after an attack of moderate duration. Generally, however, the condition is progressive, and unless the cause of the disease is removed no permanent improvement will result. In the majority of cases, however, the onset is insidious and gradual. The earliest joints involved are often the metacarpo-carpal joints of the thumb and the phalangeal or metacarpal or carpal joints of the hands, but any joint may be primarily affected. The temporo-maxillary joint is involved much more often in infective arthritis, and this is an important point in diagnosis. A localised pain in an affected joint or joints occurs, and this progresses, other joints being involved, usually in a comparatively symmetrical manner. The affected joints show swelling and signs of effusion, and there is pain on movement and usually crepitus; creaking or grating are felt. In advanced cases there may be deformity of the joint, due to the effusion and to the hyper-

trophied synovial membrane and osteophytic outgrowths. The skin over the joints, especially of the hands and feet, shows trophic changes, such as pallor, smoothness, thinning of the skin and a tendency to abnormal sweating and defective circulation. The muscles above and below an affected joint soon show marked wasting if the disease persists. Marked deformity of the joints may occur in chronic cases, and this is seen especially in the hands, feet, knees and elbows, owing to the ankylosis and contracture of tendons round the affected joints. The tendon reflexes over affected joints are usually exaggerated, owing to the excitability of the reflex nervous arc. The involvement of the joints is usually accompanied by general pains, described as rheumatic in nature, and no fever may occur, though malaise, depression, headaches, anæmia and debility are usual. Cardiac complications are absent, as a rule; and beyond the joint affections and the general malaise and ill-health often associated with marked wasting, little is found.

The mono-articular form usually occurs after adult life and often follows an injury. It may affect the hip or shoulders, and is associated with marked impairment of movement in the affected joint. The changes are those of an osteo-arthritis, and the muscles waste. The disease does not usually spread to other joints.

The vertebral form.—Pain and impairment of movement of the cervical joints commonly accompany the ordinary types of non-specific infective arthritis. In some cases the whole vertebræ may be involved, and marked fixation of the spine ensues, sometimes with deformity, resulting in the bowing commonly seen in old people (spondylitis deformans). An X-ray examination will usually reveal osteophytic changes, and the bony outgrowths sometimes involve the nerve roots, so that in these cases the pain may be so severe as to lead to the development of the drug habit.

Infective arthritis in children.—This was first described by Still and is well known. The disease is associated with fever and enlargement of the lymphatic glands and spleen, which are sure evidences of an infective origin.

Prognosis.—In an early case of non-specific infective arthritis, if the cause is discovered by investigations on the lines indicated and is then removed, the treatment adopted will in all probability be followed by marked improvement, and there is reasonable hope of a complete cure. When the active inflammatory processes have subsided, massage and passive movements of joints are likely to improve the impaired mobility resulting from the infective process. It must be admitted that in the very advanced cases, where the primary source of infection has been succeeded by secondary sources, little can be done beyond treatment adopted for relieving the distressing symptoms. In cases of long standing the inflammatory changes are often progressive in nature, and removal of the primary cause may do little good because the infective process is being carried on by a secondary intestinal infection. In an advanced case of infective arthritis, the disease is often progressive in nature, and all that can be hoped for is to arrest the progress of the inflammatory process.

Treatment.—The most important step is first to find out the cause of the infection which has given rise to the arthritis. The measures to be adopted have been already indicated. A careful and complete clinical examination should be made to discover any possible source of infection,

including an X-ray examination of the teeth and accessory nasal sinuses and bacteriological examination of the stools, the urine and naso-pharyngeal swabs.

In acute cases, with pyrexia, absolute rest in bed is essential, and complete rest of the affected joints. Local applications of heat, such as electric-light baths, or fomentations, iodine poultices, are of value. Salicylates, which are of such striking benefit in rheumatic fever, are of little use. Indeed, drugs, except for the relief of pain—such as pyramidon and phenacetin—are not of much account. Intestinal antiseptics—such as guaiacol carbonate, grs. x, t.d.s., or cyllin, ℥ iii—should be given. A new intestinal antiseptic, "dimol," which is said to have fifteen times the disinfecting power of phenol and to be non-toxic, may be taken in doses of 2 to 4 grains in keratin or sugar-coated capsules three times daily. Bier's treatment is of value until the exciting cause has been determined; an elastic bandage is placed round the limb above the affected joint, so as to obstruct the veins but not the arteries, and is left on for 20 minutes daily. In cases without pyrexia, if there are signs of active inflammation in the joint, such as redness, heat, swelling, or pain, rest of the joint is essential, and local and general treatment as above should be prescribed. Iodine is of value. Collosol iodine in doses of 1 to 2 drachms with a wineglassful of water may be given twice daily, and the French tincture of iodine, which contains no potassium iodide, may be given in doses of 6 minims in water three times daily. Iodides, if tolerated, may be given instead.

As soon as the source of infection is found, this should be eradicated, if possible. Where the teeth are implicated or an apical dental infection is present, they should be removed and placed in a sterile vessel for bacteriological examination. In removal of infected teeth it is important where many are implicated that the extractions should be effected gradually. A severe auto-inoculation may follow the extractions, so that it is often safest to remove the affected teeth two or three at a time at different operations, an interval of 2 or 3 weeks being allowed between each. This precaution is particularly necessary in patients over 50 years of age. A satisfactory way of dealing with an apical infection is Gardner's method of sterilising the infected bone area by removal of the alveolar layer over the site of the lesion and curetting the diseased tissue, and sterilisation after removal of the offending tooth. This involves a cutting operation over the gum of the affected part. This method has been used in America, but has not been much employed in this country.

Vaccine treatment is of great value, but it cannot be too strongly insisted upon that it must be accompanied by removal of the causal infection. The affected teeth should be extracted after guarding against possible contamination of the teeth removed with normal streptococcal organisms found in the mouth, and a vaccine prepared. A course of at least 3 months of vaccine treatment is usually required, with weekly and, later, fortnightly doses. It is a wise procedure also to have a bacteriological examination of the faeces made, even if a dental streptococcal infection has been found. Usually an abnormal streptococcal intestinal infection is also present in such cases. It is then an advantage to use for treatment a combined vaccine made with equal proportions of the dental and intestinal streptococci. Overdosage with vaccine should be avoided, by commencing with quite small doses, which are carefully increased. In cases where the teeth have been removed and arthritis still persists, an examination of the faeces or colon

washings will usually indicate a streptococcal infection, and in such cases vaccine treatment may give benefit. For further details, see page 45.

In chronic and subacute cases, electric light or radiant heat treatment should be given daily or on alternate days, and this should be immediately followed by ionisation with iodine ions, a 2 per cent. solution of lithium iodide being placed on the lint of the cathode. In cases where much pain is present, ionisation with salicylic acid ions is of value. Diathermy is of value for relief of pain.

When there are no signs of active inflammation and the infective cause has been removed, massage and movements of the joints are indicated. Where the joint movements are much limited, breaking down of adhesions under an anæsthetic, or suitable surgical measures may be adopted.

In pyrexial cases the diet should be mainly liquid. It must be borne in mind that most cases of non-specific infective arthritis require a diet of high nutritive value, and attention should be directed towards giving a dietary rich in vitamins. Milk, cream, eggs, the unheated juice of fresh lemons or oranges, fresh fruits and vegetables, fish, chicken and meat, may be given according to the digestive capacity of the patient. If tolerated, milk fermented with lactic acid bacilli is of value in controlling intestinal fermentation. Cod-liver oil and malt, or one of its many substitutes now on the market, may also be given with advantage.

In chronic villous synovitis where the above measures fail, opening of the joint surgically and removal of the villous outgrowths has given good results.

CHRONIC RHEUMATISM—The term chronic rheumatism is applied to many chronic affections in which pain occurs, associated with changes in the joints and fibrous structures of the body. So many different affections are loosely denominated "Chronic Rheumatism" that the term conveys no exact meaning, and it would be better abolished.

INTERMITTENT HYDRARTHROSIS

This is a remarkable and rare condition in which at periodic intervals pain and stiffness of certain joints occur, rapidly followed by synovial effusion. The swelling of the joints quickly disappears, leaving them in a normal condition, but the symptoms recur periodically after intervals of about 12 days or more. The condition is to be distinguished from infective arthritis during the course of which transient effusions may take place into various joints which clear up quickly, but in infective arthritis some of the joints show signs of a progressive arthritis with organic changes in the joints demonstrable by physical and X-ray examination, and these changes are permanent, not clearing up intermittently.

A very typical case was under the care of Dr. A. P. Luff and myself for many years. The patient, aged 64, at the age of 18 and 22 had attacks of rheumatic fever. At the age of 47 attacks of intermittent hydrarthrosis developed. Suddenly stiffness and pains occurred in the elbow and knee, followed quickly by effusion, which lasted 2 or 3 days, the symptoms entirely disappearing, but recurring after varying intervals. At first, intervals of three months elapsed between the attacks, but the intervals became less, so that recurring synovial effusions occurred, usually into the knees or elbows, at intervals of about 12 days. There was no rise of temperature with the

attacks, and between them the affected joints were perfectly normal. At the age of 53 a very severe attack followed undue exertion, and after this there was a period of freedom for 5 months. Since that time the attacks have regularly occurred at intervals of about 12 days, and have been uninfluenced by the internal administration of remedies, such as salicylates, iodides and intestinal antiseptics, such as guaiacol carbonate, and courses of thyroid extract have had no effect. Autogenous vaccines prepared from the stools and teeth have been useless. It is interesting to note that in this patient at the age of 62 definite signs of arthritis of the cervical vertebræ occurred, with changes demonstrable by X-ray examination; these were found to be associated with a dental infection, and after the removal of the affected teeth and treatment with an autogenous parodontal vaccine and the usual remedies for infective arthritis, the cervical arthritis gradually cleared up, but during this period the attacks of intermittent hydrarthrosis still occurred in the knee-joints, apparently quite independently of the infective arthritis of the neck. The recurrence of attacks of intermittent hydrarthrosis in spite of all kinds of treatment, resembles the similar recurrence of attacks in Quincke's œdema (angio-neurotic œdema), and Sir Archibald Garrod, who has made a special study of intermittent hydrarthrosis, has called attention to the association of the two diseases, one of his cases showing with the joint symptoms accompanying symptoms of angio-neurotic œdema. The prognosis in intermittent hydrarthrosis is not good as regards cure of the recurrent attacks, but these appear to have little effect on the general health, and do not lead to organic changes in the joints, though the necessity of complete rest during the attacks leads to much inconvenience and incapacity for work.

HYPERTROPHIC OSTEO-ARTHROPATHY (see p. 1262)

FIBROSITIS

A condition of chronic inflammation of the fibrous structures of the body, such as the fasciæ, aponeuroses, subcutaneous tissue, ligaments, tendons, periosteum, the sheaths of muscles, nerves and important organs of the body, may occur and give rise to pain and impairment of movement. The general term "Fibrositis" is used to cover these affections, and usually a special term is used to specify the particular part of the body affected. It includes:

Panniculitis—chronic inflammation of the panniculus adiposus, which includes "finger pads" (a localised inflammation of the subcutaneous tissue on the dorsum of the phalangeal joints) and "fibrous nodules" which may form in the subcutaneous tissues in the course of a so-called rheumatic infection, also inflammatory conditions of the fasciæ, aponeuroses, tendons and ligaments (e.g. myalgia), and of the palmar and plantar fasciæ.

Inflammation of tendon sheaths—teno-synovitis of various kinds.

Inflammation of bursæ—bursitis.

Inflammation of the nerve sheath, or peri-neuritis, as, for example, sciatica and brachial neuritis (see p. 1653).

Ætiology.—The ætiology of the various forms of fibrositis is in all probability identical with that described under infective arthritis (see pp. 1250, 1251), and a source of infection is to be sought for and eradicated in the same manner as in the case of infective arthritis. Exposure to cold, wet and damp, and the strain of unwonted exercise or undue exertion, are very likely to cause a fibrositis of the fibrous sheaths of the muscles involved. The chronic irritation and over-use of tendons and ligaments is a common exciting cause of a local fibrositis, such as occurs in teno-synovitis and the Dupuytren's contractures so often seen in coachmen and violinists. Disorders of metabolism and dietetic errors appear to play a part in the causation in some cases. Fibrositis is an exceedingly common complaint, and is one of the most frequent causes of bodily pain.

It is important that a very careful physical examination be made, and the exact site of the tender area of fibrous tissue involved should be mapped out by palpation and pressure. Care should be taken not to mistake the pain arising from some deep-seated disease for fibrositis of the overlying structures.

PANNICULITIS

In this condition the subcutaneous tissue of the panniculus adiposus may be affected in a diffuse form covering fairly large areas, or isolated small areas only may be involved. The subcutaneous tissue covering the back of the neck, the deltoids, and back is frequently affected over large areas in the "diffuse" form, and on palpation and picking up the skin and underlying subcutaneous tissue with the fingers, the thickened and tender area of panniculitis can be discovered. The small fibrous subcutaneous "nodules," sometimes found in chronic rheumatic infections, are isolated forms of panniculitis. The pathology of the rheumatic nodules occurring in acute rheumatism is dealt with elsewhere, and is of a different nature.

"*Finger pads*" are small localised areas of subcutaneous thickening, commonly seen over the dorsum of the proximal interphalangeal joints. They are composed of fibrous tissue, and are important as indicating the presence of some infection giving rise to symptoms of a chronic rheumatic type.

Patchy areas of panniculitis give rise to thickening, and even tumours of a fibro-fatty nature. Sometimes in stout people large, diffuse, painful fatty masses are formed, and a condition known as Dercum's disease or adiposis dolorosa may result (p. 477). The pain associated with the various forms of panniculitis is due to the involvement of the superficial subcutaneous nerves in the inflamed areas.

Treatment.—The treatment of panniculitis consists, firstly, in seeking for a source of chronic infection and eradicating it as far as possible. Attention to the general health is important, and over-fatigue and exposure to cold and damp are to be avoided. Daily massage gives the best results, and it is an advantage to combine it with local radiant heat. Hot baths and electric light baths are of value. Where much pain is present it may be necessary to give aspirin, phenacetin, pyramidon, etc. In "adiposis dolorosa" the above treatment may be combined with thyroid extract in suitable doses.

FIBROSITIS OF FASCIAE, APONEUROSSES, TENDONS AND LIGAMENTS

These conditions are very common, and when occurring in the neighbourhood of joints must be carefully distinguished from arthritis. Close examination will show by the impairment of movement and other signs whether a joint is involved or not. Local tenderness of the affected areas of fibrositis can usually be made out, and often tenderness of the periosteal covering of bones, especially in the pelvis, is marked. Fibrositis of ligaments and tendinous insertions is often seen. When occurring near joints a peri-arthritis may result, the joint itself being free.

1. VARIETIES OF MYALGIA.—1. *Lumbago*, where the muscles of the loins and their tendinous attachments are involved. This condition must be carefully distinguished from arthritis of the spine, from sacro-iliac disease, and from deep-seated abscesses, such as perinephric abscess or those resulting from spinal caries. In addition to the physical examination, X-ray investigation is helpful in cases which do not respond to treatment.

2. *Stiff neck* or *torticollis* affects the muscles of the back of the neck. Care must be taken that deep-seated causes of the stiffness of the neck, such as retro-pharyngeal abscess, cervical caries, or enlarged cervical glands, are not overlooked.

3. The muscles attached to the back of the skull, or those of the scapula and back may be affected, and the names cephalodynia, scapulodynia or omodynia and dorsodynia have been respectively applied.

4. *Pleurodynia*, where the intercostal muscles, and sometimes the pectorals, serratus magnus, latissimus dorsi, or other muscles attached to the ribs, are affected. The condition is usually unilateral, and gives rise to severe pain when the affected muscles are brought into action, as on coughing or deep breathing. Usually local tenderness can be elicited on palpation; but careful examination is needed to exclude such sources of pain as pleurisy or intercostal neuralgia.

5. The muscles and their attachments in any part of the body may be involved, for example, the abdominal muscles, those of the extremities, such as the deltoids or adductor muscles, and even the aryngal muscles.

Treatment.—The treatment of the above forms of myalgia consists in removal of any possible infecting cause, and local treatment, by means of massage, baths, etc., and when necessary simple remedies for the relief of pain as described.

2. *The palmar fascia* may be involved, and the resulting thickening and contraction give rise to Dupuytren's contracture.

It is rare in females, and is often associated with the chronic irritation of the palmar fascia set up by the local pressure associated with a hobby or occupation. The disease sometimes occurs in families, and may be hereditary; but frequently no apparent cause can be found for its development.

The condition usually commences as a nodular thickening of the palmar fascia opposite one of the metacarpo-phalangeal joints, from which the inflammatory condition spreads. The ring and little fingers are most commonly affected by the resulting contraction, becoming flexed at the metacarpo-phalangeal joints, the other joints usually being left in a position of extension.

Medical treatment is of little value, but removal of an infective cause of fibrositis may arrest the progress of the disease. Surgical treatment has been adopted, but the division of the fibrous bands, though temporarily relieving the contracture, is apt to be followed by a recurrence.

3. *The plantar fascia* may be involved, and this occurs usually at its insertion into the os calcis. The condition known as "painful heel" gives rise to intense pain on pressure, so that the heels cannot be put to the ground without much suffering. In some cases a deposit of bone, which can be shown by X-ray examination, forms in the affected area.

The treatment of this condition should consist, firstly, in removal of a possible cause of the fibrositis, and afterwards local treatment should be adopted. The writer has found that the application of leeches freely applied to the heel over the affected area has given the best results in obstinate cases. Massage, local applications of heat and ionisation may be used. Surgical treatment, especially when spurs of bone have been formed, may be necessary, but should be avoided if possible.

TENO-SYNOVITIS

The tendon sheaths may be affected. The condition not infrequently arises from the chronic type of infection associated with fibrositis or chronic rheumatism, and may be quite unassociated with strain or traumatism. It is not an uncommon symptom of gout. Its occurrence in dysenteric and gonorrhœal infections has been described. The flexor tendons of the hands and wrists are the most commonly attacked. Pain, swelling or crepitus results. The treatment consists in removal of a possible infecting cause. Rest, local applications of heat, and ionisation with iodine ions do good.

BURSITIS

An inflammation of the bursæ may occur as part of a fibrositis. It is important not to confuse the condition with that of arthritis, but a careful physical examination supplemented by X-ray examination, if necessary, will prevent this.

Sub-deltoid bursitis gives rise to pain round the shoulder joint, increased by movement, and very careful examination is required to distinguish it from arthritis of the joint. Bursitis is not an uncommon symptom of gout. The treatment of bursitis is similar to that of teno-synovitis.

MYOSITIS OR INFLAMMATION OF THE VOLUNTARY MUSCLES

Three forms occur—(1) the suppurative type; (2) the non-suppurative type; and (3) myositis ossificans progressiva.

1. SUPPURATIVE MYOSITIS.—In this condition there is a primary inflammation of the affected muscles associated with the local signs of inflammation and the general symptoms of a septic infection. Abscesses form in the affected muscles, which require incision, and in the pus obtained pyogenic

organisms, such as staphylococci, or less commonly streptococci, are usually found.

2. NON-SUPPURATIVE MYOSITIS.—It must be remembered that the voluntary muscles are affected in the course of other diseases. Thus, degeneration of the striped muscle, known as Zenker's degeneration, may occur in any acute infection of long duration, and it was first observed in typhoid fever. In scurvy, intra-muscular hæmorrhages are very common, and these are followed by a chronic inflammation, which usually clears up; but in a few of such cases I have seen suppuration occur. Trichinosis is accompanied by a myositis, set up by the encapsulated larvæ of the *trichina spiralis* deposited in the voluntary muscles.

Dermato-myositis is an acute or subacute inflammation of the muscles of unknown origin, which is associated with dermatitis and œdema. The onset is usually gradual, and ultimately all the muscles of the body may be involved. Pain is an early symptom, and fever of a mild intermittent type occurs. Œdema develops over the affected muscles, and is accompanied by a dermatitis of erythematous or urticarial type. Sweating is common, and enlargement of the spleen usually develops. Owing to involvement of the respiratory muscles broncho-pneumonia is a late complication. The disease is usually progressive, and generally fatal, though some recoveries have been recorded. The treatment adopted has been for the relief of symptoms, and no specific treatment is known at present.

A type of the disease in which hæmorrhages occur in and between the muscles is known as "*polymyositis hæmorrhagica*."

3. MYOSITIS OSSIFICANS PROGRESSIVA.—This is a progressive inflammatory affection of the locomotor system of unknown origin, characterised by the deposition of bony substance in the fasciæ, muscles, aponeuroses, tendons, ligaments and bones, with resulting ankylosis of most of the articulations. The disease is rare. It usually commences in early life, and is commoner in males. Three stages occur in the muscle changes. In the first stage, swelling and infiltration of the affected muscle with embryonic connective tissue occurs. In the second stage, the embryonic connective tissue becomes organised and forms ordinary connective tissue, which retracts to a hard fibrous mass. In the third stage, calcification of the fibrous mass occurs, and this becomes replaced by bone.

The muscles of the back and neck are generally the first involved, and the vertebral ligaments become ossified, so that irregular bony swellings occur, and deformity and fixation of the spine result. The upper and lower limbs are later involved, the muscles contracting and causing fixation of the joints. The muscles of mastication become finally involved and prevent movement of the lower jaw. Ultimately the patient becomes helpless and bedridden, and usually dies from some intercurrent affection, such as pneumonia, or pyæmia resulting from bedsores. The disease is always progressive, but is usually of long duration, and there may be a cessation in its progress for several years. No specific treatment of value is known.

SECTION XVII

DISEASES OF THE BONES

HYPERTROPHIC PULMONARY OSTEO-ARTHROPATHY

Definition.—A symmetrical enlargement of the bones of the hands and feet, and of the distal ends of the long bones, accompanied by clubbing of the fingers and toes, occurring in association with certain chronic diseases, in which usually the lungs are affected.

Ætiology.—The primary diseases in the course of which hypertrophic osteo-arthritis may develop are :

1. Diseases of the lungs, such as (a) Tuberculosis with cavity formation and fibroid phthisis; (b) empyema and bronchiectasis; (c) malignant disease of the lung, pleura or mediastinum; and (d) chronic pleurisy, consolidation or fibrosis of the lung, non-tuberculous in nature.

2. Congenital heart disease, and sometimes chronic heart disease non-congenital in origin.

3. Chronic diseases associated with toxic conditions, *e.g.* chronic dysentery, chronic cysto-pyelonephritis, chronic alcoholism, chronic jaundice, as in hypertrophic cirrhosis of the liver. Congenital syphilis has been stated to be sometimes a cause; but this is doubtful.

4. Chronic defects in the circulation of vasomotor origin. *e.g.* chronic forms of Raynaud's disease.

5. It is said that a neuritis may lead to clubbing of the fingers and osteo-arthritis, and pressure on the brachial plexus by a subclavian aneurysm has given rise to clubbing of the fingers on the affected side.

It appears that in the majority of cases a chronic toxæmia, in conjunction with a circulatory defect causing venous congestion, leads to the development of osteo-arthritis. This combination is found to the greatest degree in the lung diseases above mentioned. In some cases a chronic toxæmia can be excluded, as, for example, in congenital heart disease, where the circulatory defect of itself will lead to marked clubbing of the fingers; in this condition, however, the long bones are not appreciably affected, and the changes are limited to the soft parts of the terminal phalanges, the hypertrophy of which leads to the so-called "clubbing."

The disease is said to be eight times more common in males than females. All ages may be affected. The most striking examples are seen from 30 to 50; but in congenital heart disease and in chronic lung disease in children, such as bronchiectasis and fibroid phthisis, definite signs of the disease often appear in early life.

Pathology.—The bones most frequently affected are the metacarpal bones and the first two rows of phalanges. The lower ends of the radius and ulna may be also attacked, and more rarely the lower end of the humerus and the upper ends of the radius and ulna. In the lower extremities the corresponding bones are affected. X-ray examination shows a thin layer of newly formed bone diffusely spread over the shaft beneath the periosteum, and most marked just above the junction of epiphysis and shaft. The bony changes are the result of a chronic inflammation, and the thickening of the periosteum and new formation of bone beneath it may be accompanied by atrophy and rarefaction of the pre-existing bone. There are no bony changes in the terminal phalanges, the soft tissues and nails alone being affected.

Symptoms.—The onset is usually gradual, and little local pain is experienced, though stiffness and clumsiness of movements occur. Sometimes marked clubbing of the fingers may develop in a few weeks; but usually several months or more elapse before the condition is characteristic. There is a remarkable symmetry in the pathological changes, and the ends of the fingers and toes show blueness from defective circulation. The nails are large and broad and curved, both longitudinally and transversely—the so-called parrot-beak. They show longitudinal striation and are brittle and easily split. The root of the nail is raised above its bed, and if pressure is applied at the root a distinct space between them can be made out. The joints in the neighbourhood of the affected bones show swelling, from effusion and thickening of the synovial membrane. Osteo-arthritic changes in the joints are only present in the severe osteo-arthritic type. The thyroid and pituitary glands are normal.

Three types of cases are seen, but these may be only grades in the development of the extreme form of the disease.

1. *Cases showing only clubbing of the fingers, in addition to the signs of the general primary disease.*—This symptom may disappear if the primary disease is cured, as, for example, empyema.

2. *Cases showing clubbing of the fingers and painful thickening of the bones of the hands and feet, forearms and legs, in addition to symptoms of the primary disease.*

3. *The "osteoarthritis hypertrophica" type.*—The hands and feet become greatly enlarged, owing to the bony changes and thickening of the soft parts. The forearms and legs are thickened. The pelvis, sternum, ribs and clavicles may be thickened, and the vertebræ may show changes resulting in kyphosis. Osteoarthritis occurs in the parts involved, so that movement of the joints is painful and difficult. In this type of case the very remarkable changes in the bones and joints overshadow the symptoms of the primary disease.

Diagnosis.—The disease is recognised by the presence of the characteristic changes in the extremities, and by the presence of signs of one of the primary diseases already mentioned.

Infective arthritis (arthritis deformans) is distinguished by the absence of clubbing of the fingers, and by the characteristic changes shown by X-ray examination.

Acromegaly is to be distinguished by the absence of clubbing of the fingers; the kyphosis is more often cervico-dorsal, whereas in hypertrophic pulmonary osteo-arthropathy it is more often dorso-lumbar; the facial

appearance is characteristic; and in this condition symptoms and signs of pituitary disease are usually manifest.

Prognosis.—The prognosis appears to depend on the primary disease. If that can be arrested or cured, there is hope of arrest or improvement in the hypertrophic osteo-arthritis.

Treatment.—This should be directed towards the cure or improvement of the primary disease. Other treatment is symptomatic and similar to that adopted in the treatment of infective arthritis.

OSTEITIS DEFORMANS

Synonym.—Paget's Disease.

This is a rare disease and was first described by Sir James Paget in 1877.

Definition.—A chronic inflammatory condition, of unknown origin, causing enlargement and deformity of the bones affected. The disease may affect the head, the clavicles, the bones of the thorax, the spine and the long bones, or it may be limited only to one long bone.

Ætiology.—The condition usually commences at an age over 40, but has begun earlier. There are several recorded instances of inheritance of the disease, but this is exceptional. Various causes, such as syphilis, cancer, atheroma and defects of internal secretion, have been suggested; but there is no reliable evidence that these are of any importance in the causation. When the disease is limited to one long bone of the lower extremity there is sometimes a history of injury before the appearance of symptoms.

Pathology.—The changes in the bones are those of a rarefying osteitis, involving the central parts, while *pari passu* there is new bone formation beneath the periosteum, so that thickening occurs. The cause of the osteitis is not known. The bones most often involved in order of frequency are the skull, tibiæ, femora, pelvis, spine, clavicles, ribs and radii. The affected bones become much thickened, and in the case of the bones of the lower extremities the thickening is accompanied by weakness, so that deformities result. The skull becomes much thickened, and the circumference may be considerably increased. The femur is bent with its convexity forwards and the tibiæ are similarly deformed, and there may be outward as well as forward bowing. The spine becomes markedly kyphotic.

Symptoms.—The disease commences usually late in life with rheumatic pains in the legs, which may be severe, if these parts are involved; but if the skull only is affected the first symptom may be a noticeable enlargement in the circumference of the head. When the long bones and spine are affected, there may be a considerable reduction in height due to the deformities produced. The deformities already described may be noted. There is no rise of temperature, and beyond the discomfort caused by the pains and deformity the general health is usually little affected. The disease is generally progressive, but not infrequently it is limited to one long bone of the lower extremity. Death occurs from some intercurrent disease.

Diagnosis.—The disease is readily recognised when there is general involvement of bones. The bowing and thickening of the long bones of the lower extremity, the reduction in stature, and the thickening of the bones of the cranium, causing the face to assume a triangular appearance, make a

characteristic picture. Where, as is not infrequently the case, only one or two long bones of the lower extremities are involved an X-ray examination is necessary before a diagnosis can be established. In such cases careful investigation is necessary by means of clinical observation, *e.g.* the Wassermann reaction for syphilis, to exclude other possible causes of osteitis.

Treatment. The greatest care should be taken to see that the diet is rich in vitamins. Any food infection should be dealt with appropriately. Calcium should be given, in the form of lactate internally, or intramuscular or intravenous injection of 10 c.c. of 1 per cent. solution of the chloride or by other suitable calcium medication. Parathyroid extract is of value in combination with the calcium therapy. Artificial sunlight treatment is of value in raising the immunity and body resistance.

LEONTIASIS OSSEA

This is a very rare condition, in which there is diffuse hypertrophy of the bones of the skull. All the bones of the cranium and face may be affected. In one form of the disease there may be definite bony tumours appearing in the skull, which may cause pressure on the brain and give rise to characteristic cerebral symptoms.

The differentiation of this disease from the type of "osteitis deformans" in which the cranium is affected is difficult, and usually rests on the absence of involvement of other bones and the involvement of the bones of the face, which is uncommon in Paget's disease.

OSTEOGENESIS IMPERFECTA (FRAGILITAS OSSIUM)

This is a rare condition, in which multiple fractures occur in intra-uterine or infantile life. The condition is hereditary in 27 per cent. of cases (Griffith). In newly-born infants numerous fractures may be observed. In early life fractures may occur with very slight provocation, and the union resulting is usually fibrous and not bony, so that marked deformity may result. Osteo-malacia may develop in these cases, and deficient ossification of the bones of the vault of the skull and other developmental defects, such as spina bifida or club foot, may be present. When fractures are present at birth the infant will probably die soon. In cases where fractures occur after some years have elapsed there is little danger to life, but much deformity may result.

OSTEO-PSATHYROSIS (FRAGILITAS OSSIUM)

This is a rare condition, characterised by abnormal brittleness of the bones, which occurs after infantile life, and in either sex. The disease closely resembles osteogenesis imperfecta just described, and when the diseases commence in early life either term may be applied, for the two conditions are identical. It is best to reserve the term "osteopsathyrosis" for cases in which the condition commences after infantile life. Abnormal

fragility of the bones occurs in old age, and in such diseases as syphilis, cancer and diseases of the nervous system, as tabes dorsalis, general paralysis of the insane, and chronic insanity. Chronic wasting diseases may be accompanied by an abnormal tendency to fracture. These conditions are not examples of the disease under consideration, and they must always be excluded before a diagnosis is made.

Ætiology.—Osteo-psathyrosis occurs equally in both sexes. A history of inheritance from generation to generation is common, and several members of one family may be affected.

Symptoms.—General health of the sufferers is good; but fractures occur from very slight causes, such as a slight blow or fall, or even turning over in bed. Fractures of the jaw may result from the act of chewing. These lesions are not usually accompanied by pain, and union of the fragments occurs with the formation of callus. Owing to faulty positions after union, marked deformities are common.

Prognosis.—The disease does not appear to shorten life, and in some cases the abnormal tendency to fracture greatly diminishes as age advances. Great disability is, of course, experienced by sufferers from this disease.

Treatment.—This is largely precautionary, the utmost care being taken to avoid the occurrence of fractures, and when these occur they should be carefully treated on surgical lines, so that deformity may be prevented. Phosphorus has been recommended internally.

OSTEO-MALACIA (FRAGILITAS OSSIUM. MOLLITIES OSSIUM)

Definition.—A chronic disease, occurring usually in females, characterised by decalcification and weakness of the bones, with resulting bending or fracture and deformity.

Ætiology and Pathology.—*Geographical distribution.*—Osteo-malacia occurs, but rarely, in most parts of the world. In certain districts, however, it is relatively common, for example, in the Olona valley near Milan, and Calabria in South Italy, in the north-western district of Switzerland, and in certain districts of South Germany and Austria endemic areas have been observed. The disease is very much commoner in women, probably occurring at least twenty times as frequently as in males. Heredity plays no part. In the majority of cases the symptoms begin between the twentieth and thirtieth year; but occurrences earlier and later are recorded. Defective hygienic conditions and lack of suitable food are said to predispose; but the disease is not limited to the poorer classes.

There appears to be a definite relationship between the disease and the ovarian function. Its much greater frequency in women bears this out. Fehling asserted that the disease was due to a morbid condition of the ovaries, and on this assumption oophorectomy has often been performed with, in many cases, beneficial results. The ovarian theory, however, does not explain the rare occurrence of the disease in men, nor the form of osteo-malacia occurring in children.

It has been stated that endocrine insufficiency is an ætiological factor in osteo-malacia and allied conditions, and defective suprarenal function has been said to be a factor in their causation in some cases.

Infective causes have also been stated to predispose, and in some cases a severe attack of puerperal, typhoid or scarlet fever, etc., has preceded the development of osteo-malacia. The occurrence of pregnancy or repeated pregnancies appears to predispose. Morbid conditions of the thyroid and parathyroid glands have been stated to be causative factors; but this is not proven.

The bones affected are soft, and can often be bent or cut without difficulty. The bone tissue is much reduced, and the marrow is yellow or fatty, and may show hyperæmia. The periosteum is thick and hyperæmic, and the surface of the bone beneath is rough, and the bone more porous than normal. Formation of new bone does not occur, and the absorption of the calcium salts in the affected parts leaves the bony framework fibrous and decalcified. The bones most frequently affected are those of the pelvis, and next in order come the vertebræ, the bones of the thorax, those of the lower extremities, those of the upper extremities, and, lastly, the bones of the head. The pelvis may show marked deformity, the sacrum being displaced forwards and the acetabula pressed upwards and inwards. The ribs may show numerous fractures, and the sternum be much bent. The long bones may show deformity and fractures. The muscles are atrophied and may show marked degenerative changes. The joints are not affected. The ovaries have been found to show degenerative changes, but these are not constant.

Symptoms.—The onset may be insidious, so that the disease is not recognised until far advanced. Pain in the pelvic region, back, thorax and extremities occurs early, and is of an aching or neuralgic type. Tenderness on pressure over the affected bones may be present. Deformity of the spine or lower extremities may be observed, and fractures of bones from very trivial causes attract attention. The occurrence of pregnancy and the examination consequent on this lead commonly to the recognition of the pelvic deformity and the disease which has given rise to it. General weakness occurs, and the muscles show atrophy and often fibrillary tremors. The urine contains an excess of phosphates and calcium salts, and there is a tendency to the formation of renal calculi, which give rise to distressing attacks of renal colic.

The course of the disease may be fairly rapid, lasting several months, but usually it extends over several years. The patient is bedridden, and fever, sweats, wasting and cardiac symptoms occur, spontaneous fractures and bedsores adding to her discomfort and to the difficulties of nursing.

Treatment.—Attention to the general hygienic conditions is of importance. The diet should be liberal and comprise foods rich in calcium, salts and phosphorus, such as milk, eggs, fish, sweetbreads and meat. Calcium salts, especially the glycerophosphates, may be given; but though of value on theoretical grounds, they have been found to be of little benefit. Phosphorus has given the best results of any drug employed, and a course of 3 months or more is advisable. It may be given in solution in almond oil 1 in 1000, in daily doses of one teaspoonful after food, or pil. phosphori of strength 1 in 100 may be given in doses of 1 or 2 grains three times daily after food. Epinephrin and suprarenal preparations are claimed to have given good results in some cases.

Where improvement does not follow medicinal treatment and the disease

is steadily progressing, oöphorectomy is indicated. Should pregnancy occur in a patient suffering from osteomalacia, artificial abortion is justified and advisable, since the changes occurring during pregnancy usually lead to a rapid development of the disease. Lactation should not be permitted.

ACHONDROPLASIA

Synonyms.—Chondro-dystrophia; Micromelia foetalis.

Definition.—A disease usually of foetal life characterised by shortness of the long bones, trident hands and large head. It depends on interference with endo-chondral ossification, especially at the epiphyseal junctions of the long bones.

Ætiology.—The disease may be transmitted through the male line, and its occurrence in three generations has been recorded. Delivery in achondroplastic women usually necessitates Cæsarean section, and this tends to prevent transmission of the disease by the female. The disease may occur in several members of the same family. It has been stated that females are more often affected; but Rolleston's series of 100 cases showed an almost equal distribution (53 males and 47 females).

Pathology.—A fibrous tissue invasion takes place from the periosteum into the area between the diaphysis and epiphysis of the long bones, and this more or less completely prevents the endochondral ossification at the epiphyseal junction which is necessary for longitudinal growth. Consequently, growth in length of the long bones is prevented, though increase in thickness can take place from periosteal deposition. The long bones show symmetrical exaggeration of the normal curves and are strongly laid down. The scapula is dwarfed and the glenoid fossa too small for the head of the humerus. The clavicles are not affected. The fibula shows much less shortening than the tibia, so that great bowing of the former results. The pelvis is distorted and ill-shapen, the sacrum being tilted forwards. The development of bones with a membranous matrix is not impaired. The ribs show a well-marked rosary, the prominence at the junction of the rib with its costal cartilage being due to an overgrowth of bone, which surrounds the end of the cartilage in a cup-like manner. The skull is little affected in its total size, since the membrane bones develop normally. At the base of the skull early synostosis of the basisphenoid and occipital bones leads to shortening of the base and to a narrowed funnel-shaped foramen magnum.

The true causation of the above changes is unknown. A relationship to cretinism and rickets is not now accepted, and there is no evidence that tuberculosis or syphilis has any part in the ætiology. Some writers have suggested that achondroplasia is the result of a maternal toxæmia acting on the foetus, but the nature of this has not been explained.

Symptoms.—The subject of achondroplasia is more or less dwarfed. The head and trunk are about normal in size, but the extremities are much shortened, and with the arms at the sides the fingers reach little below the crest of the ilium. The humerus and femur are relatively more shortened than the other bones of the extremities, so that the proximal segments of the limbs show the most marked shortening. The hands are short and trident-

shaped, the fingers being almost equal in length. Lordosis of the lumbar spine is marked, owing to the tilting forward of the sacrum. The scapulæ are short and the fibulæ curved with the convexity outwards. The contracted pelvis in females may give rise to difficulty of labour or necessitate Cæsarean section. The general health is not affected, and the subjects of achondroplasia are usually strong and of average intelligence.

OXYCEPHALY

Definition.—A cranial deformity in which exophthalmos and optic atrophy develop.

The condition is usually present at birth, but in some instances it may develop from the second to the sixth year. It appears to be caused by premature synostosis of certain of the cranial sutures, especially the coronal and sagittal, but why this should occur is not known; as a result of the early union of the sutures the growth of the vault of the skull is restricted in its antero-posterior and transverse diameters, the necessary space for the brain being obtained by compensatory increase in the height of the skull. The anterior fontanelle appears to close later than the normal time, and its site is marked by a slight protuberance, over which the bone is thinned. The forehead is much increased in height and the supraorbital ridges are feebly marked, the hairy scalp being much raised up. Owing to the abnormal growth of the cranium and increased intracranial pressure caused by the growing brain, headaches occur, and the eyeballs become pushed forwards, causing exophthalmos. Pressure on the optic nerves and chiasma leads to progressive optic atrophy, with gradual impairment of vision. The sense of smell may be lost, owing to pressure on the olfactory bulb and nerves. The intelligence is usually not affected.

Medicinal treatment is of no value, except for the relief of headache, for which phenacetin, aspirin or pyramidon may be given. When the symptoms of intracranial pressure become marked and optic atrophy is commencing or progressing, a decompression operation is advisable.

W. H. WILLCOX.

SECTION XVIII

DISEASES OF THE SKIN

I. INTRODUCTORY

IN order that the diseases which affect the skin may be understood it is necessary to give a brief account of the anatomy, physiology and general pathology of the skin.

ANATOMY.—The skin is a fibrous structure varying considerably in thickness in different parts of the body and covered externally by several layers of epithelial cells. On section its main bulk is seen to be made up of white fibrous tissue bundles running chiefly parallel to the surface and bound together by thin fibres of elastic tissue. The surface of this fibrous mass, which is called the *dermis*, is not level but is surmounted by a number of finger-like projections, called papillæ, which fit into corresponding depressions or pits on the under surface of the epithelial covering which is called the *epidermis*.

In the fibrous stroma of the dermis blood vessels, lymphatics and nerves ramify. The *arteries* form a plexus of large vessels at the junction of the dermis with the subcutaneous fatty layer and from this deep plexus arteries pass upwards, frequently near hair follicles or sweat ducts to which numerous twigs are sent, to another superficial or sub-papillary plexus situated just below the bases of the papillæ. From this smaller vessels pass upwards to end in the papillæ. The *veins* follow a similar course in the opposite direction.

Lymph circulates freely in the spaces between the cells of the epidermis and the fibres of the dermis, but definite lymphatic vessels are also found in the papillæ and in the dermis, accompanying the blood vessels.

The *nerves* of the skin are both medullated and non-medullated. They also follow the course of the blood vessels and are distributed to the hair-follicles, sweat and sebaceous glands, blood vessels, arrectores pili muscles and to the connective tissue bundles in their passage through the dermis. Losing their medullary sheath in the sub-papillary layer some fibres pass up and are distributed to the papillæ and to the basal and mucous layers of the epidermis, while other medullated fibres end in curious whorls in the papillæ, which are called the touch corpuscles of Meissner; a few end in small ovoid bodies, known as Pacinian bodies, in the subcutaneous tissue.

The *epidermis* consists of several layers of cells, varying considerably in thickness in various parts of the body. The layer nearest the dermis consists of regular cubical cells to which it is intimately attached, and it is from this layer that the rest of the epidermis is developed; it is spoken of as the *stratum germinativum* or *basal layer*. The layers above this consist

of cells in various phases of transformation into horn cells, which are seen in their final form in the outermost layers. Above the basal layer there are several layers of large polyhedral cells with large nuclei and a spongy cell substance; they are bound to one another by fine fibrils from which they have obtained the name "prickle" cells; this is the *mucous* or *Malpighian layer*. Above this are one or two layers of lozenge-shaped cells, lying parallel to the surface of the skin, whose protoplasm contains large deeply staining granules, giving to it the name *granular layer*. Then comes a thin transparent layer, the *stratum lucidum*, and above this the *horny layer*. Here the cells have lost their nuclei and protoplasm, and consist only of a cell capsule which has been converted into a highly resisting substance called keratin; the cells are intimately bound together and can only be separated with great difficulty. Thus a strong protective layer is produced which can only be destroyed by strong acids or alkalis or by violence.

Dipping down from the epidermis into the dermis are certain epithelial structures, the hair follicles with their sebaceous glands, and the sweat glands.

The *hair follicles* are pockets of epithelium which contain in their walls all the layers of the epidermis in a modified form. They penetrate the whole thickness of the dermis and often pass into the subcutaneous tissue for some distance. The *hairs* grow from enlarged papillæ at the bottom of the pits and also consist of modified epidermis, so modified that the cellular structure is only visible on the outer layers formed of superimposed scale-like cells, the cuticle of the hair; the remainder of the hair structure consists of an outer fibrous part, the cortex, and a more succulent centre, the medulla. Hairs are present all over the skin except on the palms and soles, and vary very much in size. Their ordinary characteristics need no description. The hair follicle is inserted obliquely in the skin, and on the aspect where it forms an obtuse angle with the surface, a small band of unstriated muscle, the *arrector pili*, is found, attached below to the hair follicle near the papilla and above to the fibrous tissue underlying the surface epidermis. This muscle on contraction erects the hair.

From the same side of the hair-follicle, and lying between it and the muscle, so that it is compressed when the muscle contracts, is found a sacculated gland growing out of the follicle; this is the *sebaceous gland*. It secretes an oily substance which lubricates the hair and the skin surrounding the follicle. The secretion is produced by fatty degeneration of the cells of the gland itself, and is expressed by contraction of the *arrector pili* muscle. These glands vary much in size and in some cases far exceed that of the hair follicle; in this case they often open directly on the surface of the skin in common with the hair follicle. They are most developed on the face, back, chest and scrotum.

The other epithelial appendages are the *sweat glands*, which are found everywhere in the skin. They are tubular structures which pass down to the lowest part of the dermis or into the subcutaneous tissue and end in a coil, the *sweat* or *coil gland*, the straight portion passing to the surface being the *sweat duct*. Both the duct and gland consist of a single layer of cubical cells which becomes continuous with the basal layer of the epidermis. The duct has no special epithelial lining through the epidermis. Involuntary muscular fibres, which expel the secretion of the gland and are under the control of special pilo-motor centres, are present among the coils of the glands. The

secretion of the gland is a true secretion and is not produced by degeneration of its cells, as in the case of the sebaceous glands. Certain large sweat glands, called *apocrine glands*, occur in the axillæ, nipples and pubic region, which do, however, show breaking up of the cell protoplasm during activity.

The only other skin structures that require mention are the *nails*. These are simply modifications of the horny layer of the skin. The nail grows from that portion of the nail bed which is partly hidden by the nail fold and partly seen as the lunula of the nail, which forms a pale half-moon shaped area above that structure; this area is called the *matrix*.

PHYSIOLOGY AND PATHOLOGY.—The functions of the skin are four in number—(1) It forms a protective covering over the whole body; (2) it is an organ of secretion; (3) it is the seat of tactile sensation; and (4) it plays an important part in regulating the temperature of the body. The skin also allows of absorption, though this can scarcely be considered one of its primary functions. From the point of view of dermatology the two first functions are the most important.

The protective function is a double one, firstly the skin as a whole lying on a loose connective tissue pad, protects the deeper structures from damage by acting as a buffer; secondly, the resistant characters of the horny layer protect from irritants, not only the deeper structures, but also the layers of the skin lying beneath it, for the moist cells of the body unprotected by these dry keratinised cells would perish if exposed even to the ordinary atmosphere. Damage to the horny layer is responsible for a very large group of inflammations of the skin.

The horny layer, however, does not act quite alone: it is made more impermeable to simple external irritants by the presence of a thin layer of oil on its surface which is provided by the secretion of the sebaceous and sweat glands. As will be shown later absence or deficiency of this oily secretion renders the skin much more susceptible to external irritants. On the other hand, excessive sweat secretion from the large amount of water it contains may make the horny layer sodden, and therefore more liable to damage. Similarly, an excessive sebaceous secretion tends to make the horny layer thicker and is an excellent medium for the growth of organisms.

It must further be remembered that the horny layer does not form a complete sheet, but that innumerable invaginations which form the hair follicles and sweat ducts are present. These considerably weaken the protective power of the horny layer, and it will be found that at these spots inflammatory reactions, due to damage of this layer, are most likely to occur. It is also practically certain that absorption takes place at these follicular openings.

The secretions of the skin are the sweat and the sebum, the latter of which is the secretion of the sebaceous glands. The former is a watery fluid which contains traces of sodium chloride and other mineral salts, extractives, and a very small quantity of urea and fats. It varies very much in quantity, but normally about equals the quantity of urine voided and, therefore, is responsible for the removal of nearly 50 per cent. of the total water excreted by the body. The main function of this excretion of water is to maintain the temperature balance of the body and, therefore, in hot weather the amount of sweat is increased in order to cope with more rapid evaporation and so keep the body surface cool, the quantity of urine being correspondingly

diminished unless larger quantities of water are imbibed. In cold weather the reverse is the case.

The sweat has special interest to the dermatologist not only from its lubricating effect on the horny layer, but also from the fact that certain drugs are sometimes excreted by it, and it is possible that some of the eruptions caused by the ingestion of these drugs may be produced by their irritating action during the process of excretion by the sweat.

The sebum is an oily secretion whose function appears to be entirely that of lubricating the hairs and surface of the skin: it not only helps to protect the skin from chemical irritants, but also from the actinic rays of the sun.

The other two functions of the skin, namely, the *tactile sense* and the *regulation of temperature*, will have been dealt with elsewhere, and as they affect the dermatologist but little, they will not be further considered here.

GENERAL DESCRIPTION OF SKIN DISEASES

The bulk of skin diseases fall into two great classes, inflammations and new growths. There are in addition certain conditions which cannot be included under either of these headings, and will require special mention, namely, the disorders of secretion, of sensation, of the circulation, and of pigmentation; atrophies of the skin and certain congenital abnormalities. It will also be necessary to describe the diseases of the hair separately. As so many of the inflammations depend upon disorders of secretion, sensation and circulation, it is proposed to deal with these first. Before proceeding, however, to deal with pathological conditions of the skin, it will be useful to define the terms used in describing clinical manifestations. It must be realised, however, that these terms are used very loosely, and are only a convenient form of nomenclature.

A *macule* is a spot which is not raised above the skin; it may be vascular or pigmentary. The term is usually applied to small lesions up to the size of a pea, a larger lesion being called a "plaque" or "*tâche*." Large sheets of redness are generally called an "*erythema*."

A *papule* is a solid elevation usually not exceeding the size of a pea. If the surface is flat and smooth it is called a "plane" papule; if pointed an "*acuminate*" papule.

A *tubercle* or *nodule* is an elevation usually between a pea and a hazel nut in size. The term nodule is also used for small solid swellings in the substance of the skin and subcutaneous tissue which do not necessarily project above the surface.

A *tumour* is a swelling exceeding a hazel nut in size. It need not necessarily be solid, but this term is not usually applied to thin-walled superficial fluid swellings.

A *wheel* is a circumscribed elevation of the skin of a transitory character in which œdema is so marked as to force the blood out of the superficial capillaries and so produce a dead white elevation.

A *vesicle* is an elevation not larger than a pea containing clear fluid.

A *bullæ* is a similar lesion of larger size; in other words, a *blister* or a *bleb*.

A *pustule* is a similar lesion to a vesicle, but contains pus instead of clear fluid.

A *scale* is a lamella of the horny layer of the skin.

A *crust* is a mass produced by the drying of exudates on the skin.

An *excoriation* is an abrasion of the superficial layers of the epidermis.

A *fissure* is a crack in the skin.

An *ulcer* is a circumscribed loss of tissue involving the whole thickness of the epidermis.

A. M. H. GRAY.

II. CONDITIONS PREDISPOSING TO SKIN DISEASES

A. —DISORDERS OF SECRETION

Under this heading are included deficiency or absence of sweat and sebaceous secretion, and also excessive secretion.

ANIDROSIS OR DIMINUTION OF SWEAT SECRETION

This occurs in many diseases, but is seen in its most marked form in xeroderma and ichthyosis. It also is seen in hypo-thyroidism and in its more marked form myxœdema, in the degenerating skin of old people, and in poisoning by certain drugs, of which arsenic is one of the most frequent examples.

The milder cases of hypo-thyroidism show dryness of the skin, dryness, brittleness and thinning of the hair. They improve rapidly under the judicious administration of thyroid extract.

XERODERMIA AND ICHTHYOSIS

These two names are applied to the mild and severe types of the same disease. The condition is one of abnormal dryness of the skin owing to the almost complete absence of sweat and sebaceous secretion accompanied by an overgrowth of the horny layer of the epidermis (hyperkeratosis).

Ætiology and Pathology.—The disease is inherited and often occurs in several members of the same family. It attacks both sexes equally. The disease is usually noticed about the second year of life, but some children are born with a condition closely resembling it (*ichthyosis congenita*): these children are frequently premature and generally stillborn. There is no very definite evidence as to whether the changes in the epidermis follow the absence of secretions, or vice versa, or whether both are dependent on a common cause; possibly the overgrowth of the horny layer is an attempt on the part of Nature to compensate for the protection usually supplied by the oily secretions. Histological examination shows very marked increase in the thickness of the horny layer, which is irregular and grows directly from the mucous layer, the granular layer being absent. The sweat glands are apparently normal histologically, although they do not function, but the sebaceous glands are atrophied.

Symptoms.—In the milder cases (*xerodermia*) the skin is dry and rough,

and there may be a certain amount of branny scaling on the surface. On the extensor aspect of the limbs the hair follicles are prominent and contain small horny spines. The palms and soles are more lined than normal, while the flexures of the body show little change. The hair is dry and lustreless, and occasionally stunted and brittle, while in a few cases only down grows on the scalp.

In the more marked cases (*ichthyosis*) the body is covered with large fish-like scales which are firmly adherent. They may be thin, transparent and colourless, or thick and dark in colour (the so-called alligator skin). In these cases the trunk and extensor aspect of the limbs are most involved, the face and scalp often showing little change, though the changes mentioned above may be present. This dry skin is particularly liable to become inflamed on account of alteration in its protective mechanism.

There is another form in which the disease develops in localised sheets, lines or bands (*ichthyosis hystrix*), but this condition is closely related to the linear nævi and will be dealt with under that heading.

Prognosis.—The disease persists throughout life, and although it can be relieved by appropriate treatment it never really gets well.

Diagnosis.—The dryness of the skin, the origin of the disease in early life, and its persistence, and the presence of fine or coarse scaling with the absence of inflammation renders the diagnosis easy.

Treatment.—This consists in an attempt to replace the natural oil of the skin. Frequent warm baths, followed by the application of some oily preparation, is usually sufficient. One of the most useful preparations is glycerin. amyli, adip. lanæ hydros. āā ptes. æq., to which may be added 2 per cent. or 3 per cent. of salicylic acid if desired. Too vigorous use of soap is to be discouraged.

Some authorities recommend thyroid extract internally, on the grounds that the condition is due to deficient thyroid activity, but the results obtained have been scarcely sufficient to confirm this view.

HYPERIDROSIS

Definition.—This is a condition of over-activity of the sweat glands. It may be general or local.

Ætiology and Pathology.—Sweating in febrile illnesses is not included under this heading. The generalised forms are usually seen in adults, while the localised varieties are not infrequently seen in younger people. They are both probably due to disturbances of the nervous system, though it is difficult to say that they always occur in neurotic individuals. There is no doubt, however, that hyperidrosis is very liable to produce a neurotic condition.

Symptoms.—*Generalised hyperidrosis.*—In this condition the patient sweats excessively, often on the least exertion or excitement. The sweating may be so severe that the patient has to change his clothes several times a day—even in cool weather.

Localised hyperidrosis.—There are certain regions of the body particularly liable to excessive sweating, namely, the palms and soles, the axillæ, and the genital region and perineum. The sweating is often very excessive, and may last for a very long time; there is, however, a tendency for the

condition to diminish with age, it being most marked in the latter half of the second and the third decades of life.

The sweat allows certain saprophytic organisms to grow freely, with the result that decomposition takes place, and an extremely offensive odour develops. This is chiefly noticed in the feet, and is spoken of as *bromidrosis*. Occasionally the sweat is coloured (*chromidrosis*), due in most cases to bacterial activity.

The skin constantly soaked in sweat is subject to attacks by irritants, bacterial and otherwise, and various forms of dermatitis are frequent complications of hyperidrosis, especially the forms spoken of as *milharia rubra* and *dysidrosis* (see p. 1289).

Prognosis.—Localised cases will generally respond to treatment; but the more severe generalised cases are apt to be very persistent.

Treatment.—For the *generalised cases* frequent warm baths are required to keep the skin clean. Dabbing on a weak formalin lotion (1 per cent.) is often useful; but care must be taken not to use it too freely, as a dermatitis may be set up. The general health should be looked to, and all dietetic errors and habits liable to cause sweating rectified. Some cases benefit by the internal administration of bromides and belladonna.

The *localised cases*, when extreme, are best dealt with by X-rays. Ten or twelve doses, each of $\frac{1}{4}$ Sabouraud pastille, given in groups of four doses at weekly intervals, with intervals of one or two months between the groups, usually give a satisfactory result. Bromidrosis of the feet is best dealt with by frequent washing and change of socks, by bathing in weak formalin solution, or by washing with lysoform, or other formalin soap. The feet should then be freely dusted with a powder of talc containing 3 per cent. salicylic acid.

SEBORRHŒA

Definition.—By the term seborrhœa is meant an over-activity of the sebaceous glands, resulting in an abnormally greasy skin.

Ætiology.—This condition occurs from the time of puberty onwards, gradually diminishing as age increases. It tends to affect certain races and families, but is also influenced by the habits of individuals. Gastric disturbance, constipation, anæmia, uterine trouble and the like all tend to exaggerate the condition.

Pathology.—The condition appears to be due to some disturbance of metabolism not yet fully determined. Some authorities consider that infection by certain organisms play a part, but the evidence is inconclusive.

Symptoms.—The regions affected are the face—especially the nose, naso-labial folds—the scalp, chest and back. In the milder cases the skin is greasy; in the more severe cases it is thickened—giving rise to a muddy appearance—and the follicles are patulous. This condition Darier has labelled “la kérose.” In other cases the sebaceous follicles are plugged with semi-solid sebaceous material.

Complications.—Seborrhœa is the underlying cause of many skin affections. Acne vulgaris is merely a more marked stage of the follicular plugging noted above. Infection by certain organisms producing seborrhœic dermatitis is very common, while the skin is especially liable to

ordinary eczema and impetigo contagiosa. Acne rosacea is particularly liable to occur in seborrhœic individuals.

Treatment.—The general health must receive attention. Diet should be regulated to get rid of dyspepsia and constipation; especially should excess of sugars and starches be avoided. Iron and arsenic are indicated in anæmia, and uterine troubles should be appropriately treated. Sodium-bicarbonate in full doses is recommended as a specific by Barber.

Frequent washing with soap and water is necessary. Sulphur has a marked effect in diminishing the secretion, and especially in preventing organisms from growing in it; it may be used as a powder—sulphur. precip. 5 parts, pulv. talc to 100 parts; or as a lotion, potass. sulphurat. $\bar{5}$ i; sp. vin. rect. $\bar{5}$ ij, aquam ad $\bar{5}$ vij.

B.—DISORDERS OF SENSATION

The disorders of sensation comprise hyperæsthesia, anæsthesia and paræsthesia.

Hyperæsthesia is generally symptomatic of some organic or functional disease of the nervous system, and has little or no importance in dermatology.

Anæsthesia also is usually symptomatic; but one form occasionally comes under the notice of the dermatologist first, namely, that associated with syringomyelia. The individuals affected show anæsthesia with trophic changes in the skin of the fingers, often with whitlows and other signs of skin sepsis. Further investigation shows the lesions to be only part of a more general disease of the nervous system. This type is spoken of as Morvan's disease, and is dealt with elsewhere (p. 1606). Localised areas of anæsthesia, with redness, are frequently an early sign of leprosy (see p. 117).

Paræsthesia forms the most important group from the dermatological point of view, as it includes itching or pruritus.

PRURITUS

Under this heading are included those cases of itching of the skin in which there is no other obvious dermatosis. It may be general or local.

GENERALISED PRURITUS

Ætiology and Pathology.—The causes of general pruritus may roughly be classified as follows:

1. The presence of toxic substances circulating in the blood. For instance, in diabetes and jaundice from the presence of sugar and bile-salts in the blood. Similarly certain ingested drugs, such as opium, will cause it. It also occurs in gout and nephritis.

2. As a symptom of some blood diseases, such as leukæmia and lymphadenoma, before any skin lesions are present.

3. In atrophy of the skin in old people, the so-called senile atrophy.

4. In a large group of cases in which no cause can be found, and which are considered of functional origin.

Symptoms.—In the majority of cases itching is the only or main symptom, but others, such as tingling and burning, may be present. It may vary very much in intensity, and may be intermittent. Some people suffer most in hot weather; but it is more frequent on exposure to cold. Hot baths sometimes bring on attacks. In the more severe types the condition is most distressing, the patient rarely has any peace, but is constantly scratching, it keeps him awake at night, and as a consequence his general health suffers and he becomes a nervous wreck. In spite of this, it is extraordinary how little sign there is of scratching on the skin; some cases show a certain number of linear excoriations, but the scratch lesions are rarely as marked as they are in the localised forms and in parasitic affections. Sepsis of the skin is rarely seen.

Diagnosis.—It is essential to try and find the cause. Parasitic infection should be excluded in the first place, and then internal ailments, including the blood diseases. The presence of marked scratch lesions, especially with sepsis, suggests a parasitic origin; the special distribution of parasitic lesions will be considered under their appropriate headings (p. 1315 *et seq.*).

Treatment.—In the cases in which no definite cause can be assigned it is necessary to attend to the general hygiene of the patient. Diet requires careful regulation; alcohol, strong tea and coffee should be forbidden, as should all substances likely to produce urticaria, *e.g.* shell-fish, strawberries, etc.; hot and highly seasoned dishes and excess of nitrogenous food are better avoided. Any disturbance of digestion, especially constipation, should be treated. In bad cases sedative drugs may be required, of which bromides, belladonna, cannabis indica and valerian are the most useful. Injections of pilocarpine are recommended in dry skins. In cases of sleeplessness trional or sulphonal is useful. Opium should be avoided, as, apart from other reasons, it may increase the itching.

Local treatment depends on the conditions which excite the pruritus: for instance, in some cases baths are advantageous, while in others they increase the itching. If the skin is dry, as in senile pruritus or when associated with xeroderma, oily preparations are beneficial: glycerine of starch and lanolin in equal parts, or cocoa-nut oil with a little soft paraffin, are useful preparations, especially if 1 or 2 per cent. menthol or carbolic acid is added. Liq. carbonis detergens and liq. plumb. subacet. fort. aa $\bar{\text{z}}$ ij, and milk to $\bar{\text{z}}$ vij is often satisfactory. Most cases, however, get most relief from alkaline baths and lotions: for the latter liq. potass. $\bar{\text{z}}$ i, sp. coloniensis $\bar{\text{z}}$ i, aquam ad $\bar{\text{z}}$ vij answers well.

It is very important to see that the patient changes his undervest at night. Many patients do not do so, and this undoubtedly predisposes to pediculosis. Even, however, in cases where no pediculosis appears to be present, cases are often cured by attention to this detail.

LOCALISED PRURITUS

Certain parts of the body are liable to pruritus: these are the anus, vulva, and scrotum. Other local areas, however, may be attacked, such as the front of the ankle, lower part of the leg, thighs, back of neck and scalp.

There is a curious itchy condition, the cause of which is still obscure, which attacks the flexures of the body, axilla, elbows, groins and knees, and in severe cases the neck and face. This latter condition is very common in young children, but it may be seen, generally in a more severe form, in young adults, chiefly females.

Ætiology and Pathology.—Most of these localised cases probably start from some transitory cause, which gets better; but a vicious circle has been started, the scratching bringing on itching, and this causing scratching again. In the case of the anus, piles are a frequent cause. Vaginal discharge frequently starts a vulval pruritus, as do sugar and other irritating substances in the urine. Sweating and friction of clothes, and possibly some parasitic condition, such as *dhobie* itch, may start a scrotal pruritus.

For the other cases it is generally difficult to find a cause, and it is usually necessary to treat symptoms.

Symptoms.—The localised itching is often followed by marked changes in the skin from rubbing and scratching. The usual change noted is that called *lichenification*, in which the skin becomes thick and rigid, the lines of the skin deeper, and the area assumes a dull purplish colour, and on clearing up often leaves deep brown pigmentation. This is well seen in the patches in the flexures and on the limbs, but is modified in the moist parts, where it usually takes on a white sodden and swollen appearance, surrounded by a bright red inflammatory zone. The surface is often covered by numerous excoriations or blood-stained crusts. Occasionally these excoriations may become septic, and ulceration may occur. The symptoms are often so severe as to affect the patient's health by sleeplessness and worry.

Treatment.—The treatment recommended for generalised pruritus is often indicated in the localised cases, such as that directed towards obtaining sleep.

The first thing to do is to remove any local cause; e.g. vaginal discharges may require treatment. The bowels should be made to act freely by paraffin, saline aperients or enemata; aloes is better avoided. Irritating food, especially coffee, alcohol, curries, etc., should be interdicted. Piles may require surgical treatment, and any rectal discharge, fistula or worms should be dealt with. All the parts should be carefully washed, mild alkaline lotions or weak antiseptics being useful, and afterwards dried thoroughly and a talc or zinc oxide powder applied. Further relief may be obtained by the application of 1 per cent. ac. carbol. and camphor cream, or 5 per cent. oleatum cocainæ (B.P.C.). If these milder measures fail, the parts may be painted with silver nitrate, grs. x, sp. æther. nit. ʒi, twice or three times a week, and a bland cream or mild alkaline lotion applied.

The most radical results, however, are obtained by X-rays. Three or four doses of $\frac{1}{2}$ Sabouraud pastille given at weekly intervals to the affected area will nearly always remove the itching completely, and the secondary changes in the skin will disappear. For localised body pruritus, excellent results are obtained by painting the affected parts with crude coal tar, which is allowed to dry, and a talc powder applied. This method should not be used if sepsis is present. Further, much relief is often given by exposures to the ultra-violet rays of the mercury-vapour lamp.

C.—DISORDERS OF CIRCULATION

Only certain circulatory disorders have any bearing on skin diseases, if we do not include those disturbances associated with inflammation. Those which are referred to below usually come to the dermatologist on account of secondary changes produced in the skin.

ACROCYANOSIS

This is a condition, most frequently met with in young women, though by no means confined to them, characterised by persistent blueness of the extremities, including the hands and feet, the nose and the ears. Since the introduction of the short skirt, in the case of women the lower half of the legs is also frequently affected. The skin of the affected areas is distinctly colder than the surrounding skin. Patients are particularly liable to chilblains, and to certain types of eruption associated with the embolism of organisms in the peripheral capillaries, such as the tuberculides. The condition is apparently due to contraction of the arteries supplying the part. The causative factor is, however, unknown, but has been variously attributed to deficiency of blood calcium or to endocrine disturbance.

Treatment.—This consists in protecting the affected parts from extremes of heat and cold, massage, galvanic and faradic baths, medical diathermy and general light baths. Some cases improve by the internal administration of calcium salts, with or without parathyroid, or thyroid, and pituitary extracts, and on cod-liver oil.

CHRONIC VASCULAR STASIS OF THE LOWER LIMBS

This condition occurs in almost all individuals approaching middle life, and progresses with age. In individuals suffering from varicose veins it commences earlier. As a rule no special symptoms are produced, but if the skin of the lower part of the leg is damaged—and it is particularly prone to injury—it does not heal well, and there is a great tendency for a dermatitis to be set up. In some cases, however, the venous congestion causes itching, and if the skin in this region is scratched a moist dermatitis is liable to arise, which becomes septic, and healing does not readily occur. In these ways we have the well-known “eczema of the leg” produced. These cases frequently go on to ulceration, and the familiar chronic *varicose ulcer* of the leg is the result.

ROSACEA (*ACNE ROSACEA*)

Definition.—This is a chronic vascular congestion of the nose and central part of the face, resulting from dyspepsia and other internal conditions, and followed by secondary inflammatory changes in the skin.

Ætiology and Pathology.—The disease is common in both sexes, but rather more so in women. It begins usually after 30, but is occasionally

seen before that age. It is generally associated with dyspepsia, usually of the flatulent type, though in many cases there is no very obvious gastric disorder. Cases have been recorded in which complete achylia gastrica was present, or in which there was considerable diminution in the hydrochloric acid in the gastric juice. Uterine disturbance and the menopause are responsible for some cases. Alcohol and strong tea drinking are potent causes.

The mechanism of this vascular dilatation is not quite clear. It is generally assumed that some toxic substance is absorbed, and acts on the vasomotor system; but it is more probably a neurosis. The follicular lesions are the result of the congestion and of the increased sebaceous secretion which the hyperæmia causes, as well as of increased activity of the skin eccri.

Symptoms.—The early symptoms are either those of transitory flushing of the face, or the nose gradually becomes red. Examination shows the presence of dilated vessels on the alæ of the nose. Later the congestion becomes more marked and not only affects the nose but the adjoining parts of the cheeks, the chin and the centre of the forehead. The redness may be persistent or remittent; it is worse after meals. There is usually an increase in sebaceous secretion so that the skin becomes abnormally greasy. Scattered red papules now appear at the follicular openings, and often a bead of pus is seen in them, but no sebaceous plug or comedo. This is the typical "acne" rosacea. If the skin is very dry, this papular rash may be absent; but the whole affected area may become dry and scaly, especially if exposed to the weather, showing that the congestion renders the skin more susceptible to mild external irritants. In other cases, these inflammatory conditions are absent; but the vessels become very dilated, and much disfigurement results. In the most severe cases there occurs an overgrowth of skin and subcutaneous tissue which converts the nose into a lobulated tumour—*rhinophyma*. A number of cases show a persistent type of conjunctivitis, sometimes associated with a keratitis and corneal ulceration. The severity of the eye symptoms does not, however, appear to correspond with that of the skin lesions.

The patients complain of few symptoms except dyspepsia and flushing of the face; but the unsightliness of the condition brings them for relief.

Diagnosis.—The "acne" variety must be distinguished from acne vulgaris, by the limitation of the lesions on the centre of the face, by the underlying congestion and vascular dilatation, and by the absence of the comedo. The age is also a help, as acne vulgaris is commonest between 15 to 30. It must be remembered that sometimes the two conditions occur together. In dry "eczemas" of the face, the possibility of an underlying rosacea should not be overlooked.

Treatment.—The cause must first be dealt with. A fractional test meal will give useful information as to digestive function. Easily digested food, with a minimum of carbohydrates and green vegetables, should be ordered, little or no fluid should be taken with meals, and alcohol and strong infusions forbidden. Sod. bicarb. grs. xv to xx with a bitter three times a day after food is of great help. Dilute hydrochloric acid, M xx thrice daily, may be given in achlorhydric cases. The non-dyspeptic cases often do

well on bromides and belladonna. Ichthyol grs. iij to v (in capsules), or menthol, gr. i, t.d.s., is often useful. The bowels should be regulated.

Local treatment should be sedative in the main. In the acneiform cases, calamine lotion with 1 or 2 per cent. sulphur applied two or three times a day should suffice. In the dryer forms, ceratum galeni (B.P.C.) should be applied night and morning. When the veins are much dilated and unpleasantly prominent they may be destroyed by electrolysis or a fine pointed cautery. In the cases with much hypertrophy it may be advisable to remove some of the overgrown tissue with a knife. This can be done without leaving much scarring.

Of the other disorders of circulation which occasionally come under the notice of the dermatologist may be mentioned *Raynaud's disease* and *erythromelalgia*; but these are dealt with in other sections of this work (see pp. 974, 979).

A. M. H. GRAY.

III. INFLAMMATIONS OF THE SKIN

Having dealt with some of those disorders which predispose to inflammatory changes, it is now possible to consider the Inflammatory Diseases of the Skin. These may be divided roughly into two great classes: (1) The superficial inflammatory dermatoses, due mainly to irritants applied externally; and (2) the deep inflammatory dermatoses, due mainly to toxic substances circulating in the blood. This division is not quite so definite as one might suppose, but it is a good basis on which to work. There are, however, a certain number of inflammatory dermatoses which cannot easily be placed in either group; these will have to be considered separately.

A.—THE SUPERFICIAL INFLAMMATORY DERMATOSES

These are produced as a rule by the application of external irritants to the skin, but there are a certain number of cases in which the external irritant cannot be traced, and in which the general symptoms suggest an internal toxin. External irritants may also cause deep-seated inflammatory dermatoses, but only when they are introduced through the epidermis; thus, the puncture of the bristles of the nettle may produce an urticaria, the infection of a crack an erysipelas, a syphilitic chancre or a patch of lupus vulgaris. Nevertheless, the general rule is that a superficially applied irritant produces a superficial dermatosis.

External irritants may be classified into the following groups: (a) chemical; (b) heat and cold; (c) actinic; (d) bacterial; and (e) mechanical. This order is chosen because the clinical types can best be explained in this way. The reaction of the skin to these different irritants is generally of the catarrhal type, which is known as "eczema." This term has, therefore, been used freely to label lesions, but, as will be explained later, is used more rigidly in describing cases.

Ætiology and Pathology.—Chemical irritants applied to the skin may cause immediate, or primary, local necrosis, but only those reactions of the skin to irritants which do not cause local death of the tissues are dealt with in this section. Secondary local necrosis does, however, sometimes result from such reactions, as in the case of chronic leg ulcer following a varicose “eczema.”

Chemical irritants applied to the skin produce different forms of reaction according to the intensity of the irritant. The reactions also vary considerably in degree according to the sensitiveness or susceptibility of the subject to varying irritants. If an intense irritant, such as a mustard plaster, is applied to the skin, the whole area to which it is applied becomes intensely red, owing to congestion of the papillary vessels; the epidermis becomes œdematous, and if the action is prolonged, small vesicles or even large bullæ develop under the horny layer. Lesions of this type are spoken of as *erythematous eczema*.

If a milder irritant is applied it may only attack the follicles, which are the most vulnerable part of the protective mechanism of the skin. In this case small follicular papules are produced, which in the more acute cases are surmounted by a small vesicle. These papules tend to group together on an erythematous base forming circumscribed patches. These are the *papular* and *vesiculo-papular eczemas*. With some irritants—croton oil, for example—follicular pustulation may also occur. The pus in this case is sterile, and the lesions dry up when the irritant is removed. This constitutes *pustular eczema*.

Lastly, there is a type in which the primary lesion appears to be produced by cracking of the horny layer. It is seen, for instance, on the face in children who dribble, and on the hands of those who use soap and water to excess. Under these conditions the horny layer becomes sodden with water, and this takes place more readily if alkalis, such as soap, are present. Then the skin dries quickly, especially when exposed to the wind, hot sun or a fire, and the horny cells tend to separate from one another, exposing the delicate mucous layer. In this type scaling first appears, followed rapidly by erythema. This is one form of *squamous* or *erythemato-squamous eczema*.

All these primary reactions are liable to undergo secondary changes. Thus, fluid may exude from the surface from rupture of the vesicles and bullæ, producing a weeping eruption (*eczema rubrum*). Or, in the drier types, scaling may occur from irregular formation of the horny layer (this is the secondary type of *squamous eczema*). The moist cases may become infected with pus organisms, and the exudate may dry in the form of crusts (*eczema crustosum*). Thickening of the horny layer may occur, especially when the palms and soles are attacked, and this leads to cracking in the deeper folds of the skin (*eczema rimosum*). Occasionally in the lower extremities lymphatic obstruction and an overgrowth of the epidermis is produced (*eczema verrucosum*), or even elephantiasis may occur.

In order to classify these eczematous lesions a little more usefully, it is advisable not to speak of a superficial inflammation produced by a known external irritant as an “eczema,” but to call it a “dermatitis,” qualified by the name of the irritant which causes it, as, for example, “formalin dermatitis.” To use the word dermatitis without qualification is meaningless, and not so informing as to use the word “eczema.”

For a large group of cases in which the external irritant cannot be traced, or in which it is one of those mild irritants to which every one is exposed, such as the air, or the friction of clothes, and also for certain cases in which the lesions are disseminated over the body, the term "eczema" is still used for want of further ætiological knowledge.

DERMATITIS FROM CHEMICAL IRRITANTS

These irritants are so numerous that it is impossible in a work such as this to attempt to give a complete description of them. They may, however, roughly be divided into the following classes: (1) Due to animal poisons; (2) due to plants; (3) due to chemical agents used in medicine; (4) due to chemical agents used in trades; and (5) due to decomposition of body secretions.

1. Superficial dermatitis due to ANIMAL POISONS is rare, most of the reactions being of the deep type, as they are injected by the stings and bites of insects. Some forms of caterpillar, *e.g.* the woolly-bear, however, occasionally produce an eczematous reaction.

2. PLANTS are probably responsible for more cases than are diagnosed. The *Rhus toxicodendron* or poison ivy produces the most marked symptoms, but this plant is rarely found in this country. The symptoms are an acute erythematous dermatitis, usually with much bullous formation, attacking chiefly the exposed parts, face and hands, but also affecting the moist parts of the body, the genitals, axillæ and flexures. Japanese lacquer, which is made from one of the *Rhus* family, may also give rise to a dermatitis in susceptible individuals. The commonest plant in this country to produce a dermatitis is the *Primula obconica*, but other species of the primula may attack susceptible individuals. The lesions are similar to those mentioned above, but much less severe. Among other plants which may produce a dermatitis are *Daphne mezereum*, oleander, rue, parsnip, daffodil, and chrysanthemum, while handling certain woods, such as teak, satin-wood and ebony, may produce similar effects. In all doubtful cases of "eczema" it is well to look for the presence of one of these irritating plants.

3. Of the CHEMICAL AGENTS USED IN MEDICINE some, such as cantharides, mustard, croton oil, chrysarobin and iodine, are used to produce varying degrees of dermatitis. Others may produce it unintentionally, among these being boric acid, iodoform, sulphur, carbolic acid and perchloride of mercury. Fromalin, much used in pathological laboratories, produces a damaging effect on the horny layer, followed by a squamous and fissuring dermatitis. Sulphur, used in the treatment of scabies, is a common cause of an erythematous-squamous dermatitis on the flexor aspects of the limbs, on the abdomen and back, and is associated with intense irritation. Further, surgeons, students and nurses are apt to develop a dermatitis of the hands from the use of various antiseptics.

4. TRADE DERMATITIS.--This is very common and the lesions produced are often specific. They are very numerous, for a description of the majority of which special works should be consulted. Among the more common are the soap and water dermatitis seen in washerwomen and in those engaged in household duties. This may take the form of a dry fissuring dermatitis on the

back of the hands and forearms, or a papulo-vesicular dermatitis in the same situation. Its ætiology has already been discussed. Grocers and bakers are subject to a vesicular dermatitis of the hands, from handling sugar and dough: the so-called grocer's and baker's itch. French polishers, photographers, leather workers, etc., are frequently subject to dermatitis from articles used in their trades. These affections are usually of the papulo-vesicular type.

An acute erythematous dermatitis affecting the exposed parts of the body has been seen in those engaged in making explosives, while a more acute form caused by "mustard gas" will be familiar to those who served in France during the late war. The lesions in this case closely resemble those produced by poison ivy, the same distribution being observed.

Tar and oil acne.—Tar and various oils commonly give rise to a folliculitis, with a central keratotic plug like a comedo, associated with perifollicular inflammatory papules and pustules, and found on those parts of the body which come into contact with the irritants.

Grouped comedones.—In infants who have been rubbed with camphorated oil an eruption often occurs about the chest, neck and chin. The lesions are small black follicular plugs, closely placed, and are often associated with troublesome inflammatory complications.

Hair dyes.—An acute dermatitis of the face, particularly affecting the eyelids, is seen in persons who use certain hair dyes, especially those containing paraphenylene diamine.

Fur dyes.—Certain cheap furs, chiefly rabbit skin dyed with some of the phenylene diamine group of dyes, are responsible for a dermatitis involving the neck and chin. There is often a considerable latent period between the first wearing of the fur and the appearance of the eruption.

5. INTERTRIGO.—Decomposition of sweat and other body discharges may set up a dermatitis, usually of the erythematous type. This is best seen in fat women who are not too cleanly in their habits, the lesions being found under the breasts, in the folds of the abdomen and groins, and on the genitalia. A similar condition is often seen about the napkin region of infants. An erythema first appears, the horny layer of the skin becomes sodden and is removed by friction of the parts, and a raw oozing surface results.

Jacquet's erythema infantum.—In some children an eruption consisting of pea-sized papules occurs about the prominences of the buttocks, thighs and abdomen under the napkin; the depths of the folds escape. Occasionally these lesions spread beyond the napkin area and frequently they are capped by a vesicle or crust. It is not clear whether this is a bacterial infection or due simply to chemical irritation, but it has to be carefully distinguished from congenital syphilis. The condition is spoken of as "infantile erythema of Jacquet."

DERMATITIS FROM HEAT AND COLD

The erythema, followed often by blistering, as a result of a burn or scald, is well known. Similar but usually milder and more transient erythema may follow exposure to cold. The application of carbon-dioxide snow to the skin for purposes of treatment is a good example of the effects of extreme cold.

Erythema ab igne.—Frequent exposure to the fire produces a curious reticular erythema, followed by pigmentation.

Erythema pernio (*Chilblains*).—Chilblains are frequently seen after exposure to cold. They occur chiefly in children and old people, and particularly in those whose peripheral circulation is sluggish. The lesions are salmon-pink to purplish, ill-defined swellings, which occur chiefly on the fingers and toes, and which itch intensely. The lesions may ulcerate and produce extremely indolent sores. When the helices of the ears are attacked, as they sometimes are in old people, considerable loss of tissue may result. The treatment for this condition is the same as for "Acrocyanosis" (see p. 1280).

Trench foot.—A somewhat analogous condition was met with in the trenches in France during the Great War, in men who had to stand for long periods in the wet and cold. The feet became swollen and painful, the skin was reddened and blistering, and even necrosis occurred. The condition took a long time to subside.

DERMATITIS FROM ACTINIC RAYS

Erythema solare.—Light, whether from the direct rays of the sun or from artificial sources, produces marked inflammatory changes in the skin. The sun's rays produce first a transient erythema which subsides, leaving pigmentation; but in other cases a more persistent erythematous dermatitis occurs, associated with œdema and thickening of the skin and scaling or blistering; this is the so-called "erythema solare."

Tropical skin.—Exposure to tropical sun for many years may lead to atrophy of the skin with pigmentation and warty formation.

Prurigo æstivale.—A rather rare condition occurs in some children in which it appears that the sun's rays are an exciting cause. It consists of the appearance on the face and hands of small very itchy papules which appear during the summer and disappear in the winter. They are not always limited to exposed areas, but these regions are always the most severely attacked. The condition is a very persistent one, and any treatment, except protection from the sun's rays, has little or no effect.

Hydroa æstivale.—This is a much rarer condition than the preceding one and occurs in children suffering from hæmatoporphyria congenita, though not in these cases only. The lesions are blisters, which appear on the parts exposed to the sun's rays, and scars are left when the blisters disappear.

X-ray and radium dermatitis.—X-rays produce much more persistent forms of dermatitis than the sun's rays. If a slight overdose of X-rays is given, an erythema develops in the course of 1 to 3 weeks, which then gradually subsides. If a larger dose is given, the erythema may come on earlier and blistering may occur, which takes weeks to get well. Finally, in the still more intense burns, necrosis of the skin, with the formation of an extremely indolent ulcer, develops. In other cases, atrophy of the skin, with telangiectases and pigmentation, occurs, which may, after many years, break down into an indolent and painful ulcer, and this may in turn become epitheliomatous.

Radium may produce a similar series of changes.

ECZEMA

A description of the more specialised superficial dermatosis produced by mechanical and bacterial irritants will be left until those eruptions for which we reserve the term "eczema" have been discussed. The diagnosis and treatment of the dermatoses dealt with in the preceding paragraphs, together with that of eczema, will be considered at the end of this section. The reason for this is because it is probable that the lesions of eczema are produced, in part at least, by chemical, thermal and actinic irritants, and that pathogenic bacteria do not play an active part. Mechanical irritants do play a secondary rôle, and irritating chemical substances produced by saprophytic organisms are also concerned, but the latter are really chemical and not bacterial irritants.

Under the term "eczema" are included—(1) Certain cases of dermatitis, probably due to chemical irritants, the identity or nature of which has not been discovered. (2) Cases in which individuals are so susceptible to irritants that they react to mild stimuli that would not ordinarily be classed as irritants, such as a slight exposure to the sun, a cold wind, the warmth of a fire, or even to the friction of the clothes. (3) Cases which, having commenced with a simple dermatitis caused by an irritant, fail to get well on its removal and the patient becomes hypersensitive, so that fresh patches are produced, either in the neighbourhood of the original lesion or in other parts of the body. In fact, apart from class (1) another factor is present of which little or nothing is known, and which is spoken of as "susceptibility."

Ætiology.—Many views are held as to the causes of this "susceptibility." First there is the possibility of an inherited susceptibility or diathesis. This may be nothing more than some congenital peculiarity of the skin of which a recognisable form is xerodermia, already discussed. Abnormalities of secretion and of circulation alter the resisting power of the skin. So, probably, do certain toxic states, such as gout and rheumatism; deficient elimination, as occurring in nephritis; chronic infections, as in pyorrhœa and tonsillar sepsis; digestive disturbances and alcoholism. Disturbances of the nervous system, such as teething in infants, uterine troubles and the neuroses, may play a part.

More important, however, is the possible absorption of toxins from a local focus of dermatitis producing a hypersensitiveness or an anaphylactic condition, so that a violent local reaction occurs in the skin if the secretions from the original focus are brought in contact with other areas.

Pathology.—In eczema and superficial dermatitis the anatomical changes are most marked in the epidermis and papillary layers. There is congestion of the papillary vessels, with œdema of the mucous layer, and wandering cells may be present throughout the epidermis. Ballooning of the cell of the mucous layer occurs and minute vesicles appear. The horny layer is improperly formed, the cells retaining their protoplasm and nuclei, with the result that they shrink up on reaching the surface, from evaporation of water in the protoplasm, and so scaling is produced. This pathological condition is called *parakeratosis*.

Symptoms.—The general type of lesion found in eczema has already been described (p. 1273). It now remains to describe some of the common

types of case met with, and this is conveniently done by referring to the regions of the body affected.

Face and scalp.—Eczema of the face of a very definite type is frequently met with in infants. It usually occurs in the first year of life. It begins with a red irritable spot on one or both cheeks, and spreads fairly rapidly, so as to involve the whole face and often the scalp. In the more severe cases lesions are found on other parts of the body. The initial lesion is a red swollen patch or a group of follicular papules which later develop into an eczema of a scaly or weeping type. Itching is always intense but paroxysmal, the child rubbing the parts violently with the hands or against the pillow. In the moist variety septic infection may occur and thick yellow-green crusts form on the surface. Infantile eczema is often very resistant to treatment and may last from six months to a year, even under careful treatment; it usually dies out, however, during the second year of life.

In slightly older children a generalised eczematous condition of similar distribution, but of a septic type, is seen in association with nasal and aural discharge. Small follicular pustules are often present, and blepharitis is common. This is really an eczematized impetigo—that is, a direct bacterial infection, and not of the same nature as the foregoing, which is non-bacterial in origin.

Another common form of eczema met with on the face in children consists of sharply circumscribed scaly patches, always dry and with a surface like *crêpe*. These patches occur in the region of the mouth and nose, and can generally be traced to dribbling, running at the nose, the habit of licking the lip or smearing the face with a wet finger, or to the use of strong soaps. Some cases, however, are of streptococcal origin. It is produced by rapid drying of a sodden horny layer as described above, and goes by the name of “*pityriasis simplex*.”

In adult life, especially in oldish people, an acute erythematous eczema of the face is apt to develop. It usually appears quite suddenly. The whole face becomes acutely red and swollen; the œdema of the eyelids often being so great as completely to close the eyes. In severe cases blistering may occur; but usually the acute œdema subsides and scaling ensues. This stage may either clear up completely or a chronic eczema characterised by redness, thickening of the skin, and scaling may follow. These acute cases are often associated with a similar condition of the hands and forearms, in fact the parts exposed to the air are most likely to be affected, and this condition is particularly prone to occur in cold weather. In some cases also a history can be obtained of a coexisting septic dermatitis elsewhere, frequently on the leg, and in these cases it is possible that some absorption from this has rendered the patient susceptible. Once a patient has had an attack he is always liable to recurrences, and great care must be taken to avoid exposure to extremes of temperature. Cases of this type may be limited to the eyelids, and a troublesome and chronic condition develop.

Occasionally the papulo-vesicular type of eczema is met with on the face; it is not infrequent on the forehead, generally in men under the hat-band, and often occurs in those who perspire freely.

True eczema of the scalp, except by extension from the face, is rare, most forms of dermatitis in this region being of bacterial origin. This also applies to the ears.

Upper limbs.—The hands and forearms also being exposed to the weather, are subject to eczemas of the same type. The erythematous type frequently complicates that of the face, and runs a similar course.

Papulo-vesicular eczema of the backs of the hands and the forearms is very frequent. It is generally produced by external irritants, whose nature can often not be determined. The lesions usually consist of rather sharply circumscribed red patches covered with numerous vesicles which rupture and leave oozing, pitted raw areas of the size of a pin's head. Sometimes the whole patch is considerably swollen with œdema. There is a great tendency in this type for fresh patches to appear in the neighbourhood, and even on distant parts.

A chronic form is sometimes met with in the palm, chiefly along the deeper folds. It begins as an ill-defined red patch, and subsequently marked thickening of the horny layer takes place. Owing to its inelastic nature the skin cracks and deep fissures are produced, which are very painful and very chronic. This type is spoken of as *eczema rimosum*.

An acute vesicular form is also seen on the hands, chiefly on the palms and sides of the fingers, especially in people whose hands perspire freely. Owing to the thickness of the horny layer on the palm, these vesicles are very deep-seated, and appear like sago-grains in the skin. At first they do not rupture, but run together and form large blebs which can often be seen to be septic. The attacks usually come on quite suddenly, and the feet are often attacked simultaneously; they occur chiefly in the hot weather when sweating is profuse. This condition is called *dysidrosis* or *cheiropompholyx*, and was originally thought to be due to obstruction of the sweat ducts, with the formation of retention cysts. This is now known not to be the case, and that the vesicles are produced by an inflammatory exudate. It is probable that the skin is made sodden by excessive sweating, and this renders it susceptible to the attack of some external irritant. A similar condition has been observed from handling exploded aeroplane bombs, which shows that the condition may be produced by an external irritant.

A chronic erythematous eczema sometimes develops in the flexures of the limbs—particularly the axilla. This has been thought by some to be seborrhœic in origin, and though this has not been proved it is probably of streptococcal origin.

Trunk.—Eczema on the trunk is nearly always secondary to patches starting elsewhere, if seborrhœic dermatitis and dermatitis due to irritants such as sulphur are excluded. There is, however, one type to which reference should be made. In people who sweat much, and especially in infants, an eruption of small vesicles, each surrounded by an inflammatory zone, sometimes appears on the trunk. The lesions appear to be formed around the sweat duct openings. This condition is called *miliaria rubra*, or *prickly heat*, and is probably of the same nature as the vesicular eczema of the hands, the mouths of the sweat follicles being softened by the sweat and some irritant, possibly a bacterial irritant, causing an inflammation.

The nipples are sometimes the seat of an eczema; but this is nearly always of external origin, either from careless treatment during suckling, or from injury from stays.

Genitals and anus.—The moist areas of the genital and anal regions are liable to be attacked. These are not infrequently secondary to a pruritus,

a traumatic dermatitis being produced. On the anus and vulva, thickening of the skin, called *lichenification*, is most common, and has been already mentioned. The scrotum is occasionally the seat of an erythematous dermatitis very distressing to the patient, and very intractable.

Lower limbs.—A special form of eczema is very common on the lower part of the legs. It is associated with chronic vascular stasis. It is generally met with in middle-aged or old people, but is frequently seen in younger persons who suffer from varicose veins, hence its designation *varicose eczema*. It begins either from an infected abrasion which does not heal, or from scratching an itchy leg. Once started the inflammation spreads, as the condition of the skin does not favour resolution. The extension is often due to ill-devised dressings which further lower the resisting power of the skin and favour the retention of discharges. An extensive weeping or crusted dermatitis, therefore, follows, and this is rarely confined to the leg on which it starts, the other soon becoming infected, probably from contact in bed. Owing to the poorly nourished condition of the skin, ulceration is very prone to occur, and thus the chronic varicose ulcer, so familiar to the out-patient department of any hospital, develops. These cases are particularly prone to spread to other parts of the body by the mechanism referred to above.

The feet are subject to the same type of acute vesicular eczema as the hands.

The nails.—The matrix of the nails may be involved in an eczematous process affecting the hands and feet, and may either show a marked irregularity of growth, with roughening of the surface of the nail, or the nail-plate may be pushed up from the nail-bed by parakeratosis beneath.

Diagnosis.—Keeping in view the types of eczema already described, the diagnosis of the lesions should present little difficulty; to determine the cause, however, is not so easy. Efforts must, however, first be directed to try and discover an irritant, and if it cannot be found, or if it appears to be one of those mild irritants which do not normally produce a skin reaction, the cause of the patient's susceptibility must be investigated. These causes have already been discussed and require no repetition. As to the nature of the irritant, some help is obtained by the type of reaction and by its distribution; for instance, in an acute eczema affecting the face and hands, exposure to the wind or sun or to some irritant, as the primula, is suggested. With trades certain parts of the body tend to be especially exposed. Lesions affecting the exposed parts and the moist parts of the body suggest some strong volatile irritant, such as rhus poisoning.

Acute erythematous eczema has occasionally been mistaken for erysipelas; but the absence of a sharp line of demarcation, a slowly spreading edge and high fever, should render the diagnosis simple. Acute giant urticaria of the face is unassociated with redness or vesication. The lesions of erythema multiforme are smaller, more sharply defined, and deeper-seated.

The squamous forms have to be distinguished from seborrhoeic dermatitis; this is often difficult, but the characteristic features of this latter disease will be considered later.

Ringworm of the glabrous skin tends to occur in circumscribed circular patches or rings, and the fungus can easily be found under the microscope. A special form occurring in the groins is characterised by its bilateral symmetry, its sharp spreading edge, and the presence of fungus in the scales.

Pityriasis rosea in extreme forms may lead to confusion, but the acute generalised onset, and the presence of some of the typical oval lesions, with a collarette of scales attached about a millimetre from the free edge, will usually settle the diagnosis.

Psoriasis is rarely confused, owing to its characteristic distribution on the extensor aspects of the limbs, its usual sharply defined patches, and the dry silvery scaling, seen even in the smallest papules. A few cases, however, of isolated patches made up of small aggregated psoriasis papules may be very difficult to distinguish from localised patches of squamous eczema.

The moist forms have to be distinguished from *impetigo contagiosa*. In this disease, however, the vesicles are larger and rarely seen, while the presence of isolated crusted lesions of varying size, with little or no inflammatory zone surrounding them, is characteristic.

The vesicular eczemas of the hands and feet may be caused by a ringworm fungus. This should always be suspected in the chronic spreading cases, and must also be looked for in the acute cases. The diagnosis is made by finding the mycelium of the fungus in the walls of the vesicles—a task not always easy. A curious type of fissuring eczema between the toes is almost invariably caused by a ringworm fungus.

The eczemas found in the course of animal parasitic affections, such as pediculosis and scabies, will be dealt with later.

Prognosis.—This is always uncertain. Most cases of dermatitis due to an external irritant applied on a single occasion get well readily when the irritant is removed. Those caused by the repeated application of the same irritant, as in trade dermatitis, are apt to be more persistent, while recurrent attacks may be extremely troublesome. Once the skin has been damaged subsequent attacks are more common and more resistant to treatment.

Those cases in which some underlying susceptibility exists are always apt to be resistant to treatment.

Treatment.—*Prophylactic.*—This depends on the search for the irritant, and its removal. The latter is not always possible in case of trades; but much can be done to insist on scrupulous cleanliness. It must not, however, be forgotten that the use of strong soaps, soda and turpentine to remove traces of a man's occupation are often the cause of the dermatitis. In cases where these substances have to be used, by washerwomen, etc., the use of a cold cream or some glycerine preparation to replace the grease of the skin will prevent a good deal of trouble.

Eczematous subjects should protect themselves from the sun, cold wind, and heat of the fire.

Local treatment.—This applies equally to the cases of dermatitis due to known irritants, and to those we have labelled "eczema." The main treatment in the early stages, after removing the cause, is to protect the skin and to provide soothing application to allay the inflammation. The use of soap and water will generally have to be forbidden.

In the early and acute stages lotions are most suitable, grease in any form being badly tolerated. Calamine lotion can be applied frequently and allowed to dry on the skin, the powder it contains forming a protective dressing over the surface; it is best used in the acute erythematous and papulo-vesicular form in which there is not much oozing. In the weeping cases, lead lotion applied on linen and kept moist is more suitable; it forms

an insoluble albuminate of lead which acts as a protective layer. If, however, much sepsis is present, it is well first to use a mild antiseptic, baths of 1 in 4000 permanganate of potash, or lotions of 1 in 4000 perchloride of mercury, or 1 in 1000 acriflavine being very suitable. If these lotions dry the skin too much 3 per cent. glycerine may be added.

As soon as the acute stage has subsided oily preparations are better. It is well to begin with one containing a considerable percentage of water, the *lin. calaminæ* (B.P.C.) or *linimentum calcis* being the type. *Ichthyol*, 5 per cent., may with advantage be added in most cases, and if the itching is severe 1 per cent. to 2 per cent. *ac. carbolic*. Later the water can be given up and either pure oily preparations as *lin. calaminæ co.* (B.P.C.), or ointments used. These latter are not satisfactory if there is much discharge; but this can be checked by painting the surface once every second or third day with 2 per cent. to 3 per cent. silver nitrate in *sp. æther. nit.*

Once the chronic stage has been reached pastes are the best means of applying medicaments. Zinc paste consists of zinc oxide, 25; *pulv. amyl.*, 25; *paraff. moll.*, 50 parts, and makes a firm dressing when spread on linen or lint. It not only affords good protection, but allows a certain amount of absorption to take place.

If the chronic cases do not respond to treatment stimulating preparations are required, and can be incorporated in the zinc paste. *Ac. pyrogall.*, 1 per cent. to 2 per cent.; coal tar, 1 per cent. to 5 per cent.; or oil of cade, 5 per cent. to 10 per cent., are useful, and where there is thickening of the horny layer 1 per cent. to 3 per cent. *ac. salicylic* should be added. Chronic dry cases, and even moist ones, if not septic, often do well if painted with crude coal tar which is allowed to dry on. X-rays, $\frac{1}{3}$ rd of a Sabouraud pastille dose, repeated 3 or 4 times at weekly intervals, are extremely valuable in resistant cases, and cause rapid disappearance of the lesions.

In septic cases the crusts should be removed by warm oil or starch poultices, and a weak mercurial or flavine lotion first applied, and afterwards a zinc paste containing 3 per cent. ammoniated or yellow oxide of mercury.

The gelatine paste of Unna is very useful in the chronic eczemas of the leg, after any sepsis has been removed by antiseptic dressings.

For facial eczema of infants, 3 per cent. crude coal tar in zinc paste, spread on a mask and continuously applied, is of great value; or the special tar paste devised by White of Boston, U.S.A., may be employed.

General treatment.—The patient must be examined for any conditions liable to lower his general resistance. Septic foci, such as pyorrhœa, or tonsillar sepsis, should be removed. In the more acute cases it is advisable to put the patient on milk diet, and to keep him in bed. In the less severe cases a light diet, the avoidance of alcohol, strong coffee and tea, hot and highly seasoned dishes, shell-fish, salted meats and cheese, should be prescribed. Constipation should be dealt with, while intestinal fermentation may be met by the exhibition of salol or salicylate of bismuth, *grs. x* to *xv*; *ichthyol*, *℥ij* to *v*; or *menthol*, *gr. i* in capsules three times a day. In gouty subjects alkaline waters and colchicum are indicated.

In the infantile facial cases, the children are usually overfed and some reduction in diet is often required.

In debilitated cases cod-liver oil is of value, while arsenic and iron are

helpful when anæmia is present. In acute cases *vin. antimoniale*, ℥ v, t.d.s., has been much recommended.

Sleep is often disturbed, and will require sedative drugs to allay itching, and in the worst cases hypnotics: bromides are useful for the former, while for the latter sulphonal, trional and chloral hydrate are among the best. Morphine should be avoided, owing to the prolonged nature of the cases and to its tendency to increase itching.

DERMATITIS FROM MECHANICAL IRRITANTS

Acute dermatitis due to mechanical irritation is best seen in the redness and blisters found on the hands after rowing or on the seat after riding, in those unused to these exercises. The chronic form shows itself as a thickening of the horny layer as seen in the callosities on the hands and feet. The form of dermatitis of mechanical origin, however, which requires special attention here is that produced by the fingers and finger-nails.

SCRATCH ERUPTION

Constant friction applied to a localised area produces changes in the skin of a characteristic type. The skin becomes thickened and loses its elasticity; the folds and lines are much exaggerated, and the angular areas of skin intervening become prominent and shiny, resembling the papules of lichen planus; the colour may be the same as the normal skin, or red, but generally purplish, and sometimes the surface is finely scaly or warty. In old-standing cases much brown pigmentation may be present. This condition is spoken of as "*lichenification*," and is seen at its best in localised pruritus, already described on p. 1278.

When general irritation is present the scratch lesions are more diffuse. The finger passing over the skin causes contraction of the *arrectores pili* muscles and the follicles are erected; the next sweep of the finger-nail scrapes the top off the erected follicle and a spot of blood appears, which dries as a blood-stained crust. In bad cases, linear excoriations are produced, consisting of a line of blood-stained crusts. If sepsis supervenes, typical *impetigo contagiosa* lesions are produced, and these are particularly common in children; in other cases "*eczematisation*" occurs—that is, the inflamed papules group together to form a patch or patches, which may be dry and scaly or may weep. Patches of lichenification may also be found mixed with other scratch lesions, while in the most severe cases, *ecthymatous* lesions, boils and linear ulcers may occur.

CALLOSITIES AND CORNS

These are localised overgrowths of the horny layer, the result of local mechanical irritation. A corn differs from a callosity in that the central portion shows a much greater degree of overgrowth than the periphery, and forms an inverted horny cone which presses on the sensitive dermis, producing much pain. A corn may develop from a callosity, but frequently arises independently.

Symptoms.—*Callosities* are seen as a painless thickening of the horny layer over the ball of the foot and on the palms of the hands, in the latter situation especially in manual workers. They may also occur in other situations.

Corns may be of two kinds—(1) the hard, and (2) the soft. The former are painful, horny elevations, chiefly seen on the feet, and especially in people who wear badly fitting boots. The common sites are on the dorsal surface of the little toes and on the plantar surface of the great toe and over the head of the first metatarsal bone. If the surface layers are removed with a razor a central “core,” often stained black or dark brown from hæmorrhage, will be seen.

Soft corns are found on the lateral aspects of the toes in the interdigital spaces. They are usually lentil-sized raised swellings, covered with sodden epidermis and intensely painful. When this superficial epidermis is removed the horny plug can be demonstrated. It is well to remember that soft corns are frequently found in association with interdigital ringworm.

Treatment.—*Callosities* require no treatment. The principal point in the treatment of corns is to remove injurious pressure; this can be done firstly by fitting suitable boots, and secondly by taking pressure off the corn by wearing a ring of spongiopiline around it. The surface horny layer should be pared down with a sharp knife or razor and 10 per cent. salicylic acid plaster applied or salicylic-acid collodion painted on, the softened horny layer being removed daily. Soft corns are treated by the application of 10 per cent. salicylic collodion, followed by bandaging the affected toe to prevent friction with its neighbours. Frequent washing of the feet is necessary, and the interdigital spaces should be kept dry by powdering freely with talc powder, to which 3 per cent. salicylic acid may be added if sweating is a marked feature.

DERMATITIS ARTEFACTA

This is the name given to self-inflicted lesions of the skin. These are usually found in hysterical individuals, who produce them in order to induce sympathy, or in persons who are endeavouring to exact compensation or to avoid some unpleasant duty.

Symptoms.—The lesions are produced by various means, such as friction the application of strong acids, or alkalis, or of blistering fluid, by heat or by the aid of some sharp instrument. All stages from simple erythema to actual destruction of the skin may occur. They may be single or multiple, but are found on parts of the body easily accessible to the hands, and especially to the right hand (in left-handed people to the left hand). The lesions are very characteristic, especially those in which a liquid agent has been used. They have very sharp edges and the outline is angular, unlike that seen in any ordinary skin eruption; and not infrequently irregular patches near the main lesions have the appearance of having been produced by a spilt liquid. In addition, it may be noted that in the case of the malingerer the artefact may simply consist of keeping open an already existing lesion.

In hysterical cases *anæsthesia* of the palate has been frequently noted.

Treatment.—For effective cure the patient must be kept under observation, and caught in the act of producing the lesions. This may put a stop

to further activities. Otherwise, occlusive dressing and mental treatment are required.

DERMATITIS FROM BACTERIAL IRRITANTS

Many different organisms are capable of producing dermatitis of external origin, and the eruptions produced are usually characteristic of the organism causing them. These will be described under the organisms concerned.

STREPTOCOCCAL INFECTIONS

The streptococcus tends to produce a serous exudate into the skin. If it is introduced into the dermis through a crack or puncture, a serous and cellular exudate is produced, which is known as *erysipelas*. If the attack is more superficial, the effusion takes place under the horny layer and blisters are produced. The most common of these superficial infections is Impetigo contagiosa.

IMPETIGO CONTAGIOSA

Symptoms.—This is an affection chiefly seen in children. It affects mainly the exposed parts, such as the face and hands. The initial lesion is a small pea-sized clear vesicle, which, owing to its superficial position between the horny and mucous layers, has an extremely thin wall and ruptures very easily. Before rupture, however, the fluid often becomes turbid, and if cultured in this condition contains both streptococci and staphylococci. If cultured, however, in the very early stages, pure growths of streptococci may be obtained. Once ruptured, fluid exudes freely from the base of the blister and dries as a crust. The crusts vary in thickness and character according to the amount of secondary infection, being thin and amber-coloured if little secondary infection is present, but thick and greenish if it is considerable. Usually the lesions are numerous; they are asymmetrical and obviously spread by local inoculation.

When the lesions occur in folds, such as at the angles of the mouth or nose and behind the ears, a troublesome fissure is likely to form and generally crusting is absent, the fissure being surrounded by a moist, sodden, red area.

The disease is very contagious and children inoculate one another freely, any slight abrasion being sufficient to allow the entrance of the infecting organism. One particularly common cause is pediculosis capitis, and in this case the scalp is usually first affected. In all cases of impetigo of the scalp or back of the neck, search should be made for pediculi.

Occasionally the blisters do not rupture early, but spread centrifugally, flattening down in the centre as they progress, and leaving a ring-like bullous margin (*impetigo circinata*). In other cases a large number of bullous lesions appear very rapidly, with little or no crust formation (*impetigo bullosa*).

Any of these varieties may occur in adults, but the crusted form has generally smaller crusts than in children. One of the most frequent areas to be affected in adults is the beard region, and impetigo contagiosa is one of the forms of so-called "barber's rash."

Diagnosis.—This is usually easy. The presence of scattered crusts, with little or no surrounding erythema, and the occasional small, very thin-walled blister, and an asymmetrical distribution chiefly on the exposed parts, is unlike any other condition.

Treatment.—In most cases the treatment is easy. The crusts should be removed by bathing in warm water or by warm olive-oil compresses, or in bad cases by starch poultices, and the raw surface covered with 2·5 per cent. ammoniated mercury ointment. In the more resistant cases, it is advisable to incorporate the ammoniated mercury in Lassar's paste and spread this on lint and tie it on. The acutely spreading bullous form is best treated in the first instance by pricking the blisters and fomenting with 1 in 1000 acriflavine lotion. In very resistant cases, injections of mixed strepto- and staphylococcal vaccine have proved useful, but are rarely required.

PEMPHIGUS NEONATORUM

This is a form of bullous impetigo seen in newly-born infants and is characterised by the presence of varying-sized blisters on the skin.

Ætiology and Pathology.—Pemphigus neonatorum has precisely the same cause as impetigo contagiosa, but produces its characteristic features on account of the ease with which the horny layer separates from the underlying mucous layer in small infants. Infection is usually conveyed on the fingers of the mother or nurse. Pure cultures of streptococci can often be obtained from the bullæ in their early stages, though in some cases the *Staphylococcus aureus* appears to be the causative agent.

Symptoms.—The eruption usually appears in the first few days of life. A clear blister appears, which rapidly increases in size, and others soon occur in the neighbourhood. There is little or no tendency to crust formation, though the blisters frequently rupture, the raw surface being protected by the loose blister wall which lies over it. Blisters vary in size from a pea up to a florin or larger, and in severe cases may be very numerous, covering practically the whole surface of the body. The lesions may commence on any part of the body, but are frequent about the napkin area. In the most severe forms the horny layer is so rapidly separated over large areas of the body that blister formation is not an obvious feature. This variety is known as *dermatitis exfoliativa infantum* or "Ritter's disease," and ends fatally in a large proportion of cases.

Diagnosis.—The pemphigoid syphilide must be distinguished from pemphigus neonatorum. In the former condition the eruption is symmetrical, is chiefly found on the prominences of the buttocks, on the palms and soles; other symptoms of syphilis are present, such as wasting, snuffles, fissures at the angles of the mouth, and other syphilitic skin eruptions. A Wassermann reaction will in doubtful cases settle the diagnosis.

Prognosis.—Mild cases respond rapidly to treatment, but in the more rapidly spreading cases the prognosis is always grave.

Treatment.—The bullæ should be opened and their contents absorbed with cotton-wool. Strips of lint soaked in liniment. calaminæ (B.P.C.), to which 1 or 2 per cent. of ammoniated mercury has been added, should be applied, and changed three times a day or more often if necessary. The child should be well wrapped up, to prevent loss of heat.

ECTHYMA

In this condition local gangrene of the skin occurs and an ulcer, surrounded by a deep inflammatory zone and covered by a crust, is produced. The lesions are not always of streptococcal origin, but may be brought about in various ways; but as they have some resemblance to impetigo contagiosa, it will be well to describe them here.

Ætiology and Pathology.—The type seen in children is often of streptococcal origin and begins as an impetigo. Scratching or a debilitated condition of the patient allows of a more violent reaction, and necrosis occurs. The frequency with which ecthyma is associated with urticaria papulosa, scabies and pediculosis points to trauma as an ætiological factor. The large round adult type, referred to below, is nearly always preceded by a boil, which is a staphylococcal infection, while the linear type can be shown to be produced by violent scratching, to which is added secondary pus infection.

Symptoms.—All varieties are most often seen on the legs and buttocks. The lesions are usually discrete and few in number, but there are exceptions. They have the appearance of impetigo contagiosa lesions, but there is a wide congested area around the crusts, and these latter are not "stuck on" but firmly fixed. On removal an ulcer the size of the crust is found. This type is usually found in children. Another variety is seen in adults especially, in association with pediculosis vestimentorum, and was seen very frequently during the late war. Two types are seen: the large circular type, which has the characters of those mentioned above, but the individual lesions are larger, and the linear or gutter-shaped type, in which long ulcers, often 2 or 3 inches in length and covered with a thick crust, are present.

Diagnosis.—This has to be made from the ecthymatous syphilide, usually a late tertiary manifestation. In this condition there is a tendency to grouping of the lesions, and they are of a more chronic type. Other syphilitic manifestations, a positive Wassermann reaction, and rapid response to anti-syphilitic remedies will settle the diagnosis.

Treatment.—Local treatment is similar to that of impetigo contagiosa. The crusts should be removed by baths or starch poultices, and a Lassar's paste with 3 per cent. ammoniated mercury tied on. In the adult cases, after the sepsis has been removed by 1 in 4000 perchloride of mercury or 1 in 1000 acriflavine dressings, Unna's paste should be applied and changed every 2 or 3 days until healing takes place. Where debility and malnutrition are present, suitable internal treatment must be resorted to, cod-liver oil and malt, and the preparations of iron, arsenic and the phosphates being most useful.

SUPERFICIAL STREPTOCOCCAL DERMATITIS

Certain forms of circumscribed, dry, superficial dermatitis, with fine branny scales, are sometimes seen in association with impetigo contagiosa and appear to have the same origin. In fact, all stages between the two conditions can be traced. In other cases dry scaly patches are found without any impetigo contagiosa lesions, and streptococci have been isolated from them. These cases are sometimes indistinguishable from the scaly patches which occur on the faces of children, and which are described in the section

on Eczema (p. 1288), where it is suggested that moisture and soap play the chief part in their production. It would thus appear that the streptococcus may produce lesions clinically identical with those produced by these physical and chemical causes. It has been thought also that some forms of circumscribed scaly dermatitis found about the neck and trunk, and also in the flexures of the limbs, and which have in the past been loosely grouped as seborrhœic dermatitis, are probably of streptococcal origin, but further investigation is necessary in order to group them clearly.

These lesions are often resistant to treatment. They are frequently associated with a good deal of itching, and are often followed by secondary changes due to friction, namely, "lichenification" and "eczematisation."

Treatment.—The early cases sometimes respond well to applications of dilute ammoniated mercury ointment; others, however, do best on ac. salicyl., grs. xv; liq. picis carbonis, ℥ xv; past. zinci ad ʒi. Once a condition of lichenification is established, the treatment should be on the lines laid down for local pruritus (p. 1279).

STAPHYLOCOCCAL INFECTIONS

Staphylococcal inflammations differ from streptococcal in that they tend to occur in the neighbourhood of the hair follicles, and are accompanied by a purulent exudate from the start, and not a serous exudate, as is the rule with the latter. Several varieties of pustular folliculitis occur.

BOCKHART'S IMPETIGO

This is the name given to a superficial pustular eruption of staphylococcal origin seen in connection with the hair follicles.

Symptoms.—The lesions consist of small beads of pus situated quite superficially at the mouths of the hair follicles, each being surrounded by a narrow red zone. Generally the hair can be seen penetrating the centre of the pustule. There is no tendency for the lesions to run into one another, each remaining quite distinct. Usually groups of them occur in localised areas, but sometimes their distribution is very extensive, cases occurring in which almost every stout hair is surrounded by a pustule. The most frequent sites are the fronts of the thighs, the legs, the genitals and the backs of the forearms. A very troublesome variety is seen on the scalp of children between the ages of 2 to 5, the infection being usually derived from a discharging ear or nose. The whole scalp is affected, and the condition is combined with a superficial septic dermatitis which affects also the face, and often spreads to other parts of the body. Ciliary blepharitis is a frequent complication. This is the condition which was formerly described as *pustular eczema*. The majority of localised cases occur in conjunction with other forms of pyoderma; they are seen in scabies and pediculosis, and also in people suffering from boils.

Treatment.—The general health of the patient must be attended to, and all local foci of sepsis dealt with on surgical lines. A search for parasitic infestation must be made and appropriate measures adopted. In the localised cases, the pustules should be punctured, and 1 in 1000 acriflavine lotion applied; if this proves too irritating, lead or calamine lotion should be used, the accumulation of powder from the latter being bathed away daily with a

weak alkaline lotion. Mercury lotions are better avoided, as they tend themselves to produce follicular pustulation.

The more extensive cases are very resistant to treatment. Shaving the affected areas, followed by the application of mild antiseptic lotions or sedative lotions and alkaline baths, is sometimes effective. Staphylococcal vaccines should be tried in addition, and in some cases stannoxyl (an oxide of tin) and injections of colloidal manganese have given good results. In the pustular eczema of the scalp, the crusts should be removed with warm oil or starch poultices, and the lotions indicated above or acriflavine 1 in 1000 in liniment. calcei applied. At the same time nasal and ear discharges must be appropriately treated. These cases take a considerable time to cure, but the results repay the attention necessary.

FURUNCLE

Boils or furuncles are deep-seated infections of the hair follicles with the *Staphylococcus aureus*.

Ætiology and Pathology.—The exciting cause of a boil appears to be the presence of virulent staphylococci in the hair follicles which occasion an intense reaction sufficient to cause local necrosis. This is the more liable to occur where the skin is thick, owing to the pressure exerted on the dense fibrous-tissue bundles and the consequent obstruction to the circulation. Scratching, which conveys the causative organism to the follicles and damages their orifices, predisposes to boils, as is seen by their frequent occurrence in parasitic affections. Lowering of tissue resistance, such as occurs in diabetes and in other conditions of lowered vitality, is also a predisposing cause. In other cases it is possible that a condition of allergy and hypersensitiveness to the staphylococcus is present, and this probably accounts for the constant recurrences which occur.

Symptoms.—Boils may attack any part of the body where hair follicles are present, but are most commonly seen on the neck, back and buttocks, regions where the skin is thick and exposed to pressure and friction. The lesions are usually single or few in number, but they tend to recur with great persistence, and recurrences may continue for a long period. The patients attacked are often in a low state of health. Boils are particularly liable to occur in diabetics, and the urine of patients should always be examined for sugar. A boil commences as a deep, tender infiltration, which rapidly increases in size so as to form a painful red swelling, up to an inch in diameter, which projects above the surface of the skin. Later, a small pustule appears in the centre of the swelling and this eventually bursts, exuding a small quantity of pus, which relieves the pain. Later still, a small slough separates from the centre of the swelling, and when this has come away the boil heals, leaving a pitted scar. Some boils, however, subside without bursting. Sometimes the earliest lesion is a superficial pustule, which is followed by the rapid formation of an inflammatory zone. Later, infiltration of the deeper tissues follows, and a slough forms and is discharged, as in the first-mentioned type.

Treatment.—The general condition of the patient must first be dealt with on general lines. Certain internal remedies, such as yeast and calcium sulphide, have occasionally proved of value, but are generally useless.

Vaccines of *Staphylococcus aureus* produce excellent results in some cases, but cannot be looked on as a specific. Stock vaccines seem to be as successful as autogenous. Injection of colloidal manganese, suggested by McDonagh, beginning with 0.5 c.c. and repeated twice a week, in slightly increasing doses, for 3 to 4 injections, produces the most dramatic results in certain cases; others, however, are completely resistant. McDonagh has recommended alternation with intramine, but the results do not appear to be materially altered by this routine. Stannoxyd, given by the mouth 2 to 3 tablets t.d.s., has also been claimed to produce excellent results. Local measures are of great importance. The skin should be cleaned up with baths, medicated or otherwise, and the affected areas dressed with 1 in 4000 perchloride of mercury, picric acid, or 1 in 1000 acriflavine. Boric acid fomentations should be avoided, as they spread the infection. Boils should be opened early—as this reduces the amount of necrosis—and treated on surgical principles.

CARBUNCLE

A carbuncle is a boil or group of boils in which the subcutaneous tissue has become involved in the infective and necrotic process.

Symptoms.—Usually only a single lesion is present. It may at the commencement appear like an ordinary boil, but the spread is rapid, and soon a large, red, indurated, painful area is produced. The lesion may attain a diameter of many inches. After a few days numerous points of pus appear on the surface of the swelling, and these burst and exude pus. The bridges of tissue between these openings may subsequently break down and reveal a large slough, which may take several weeks to separate if not removed by surgical means. Fever and other constitutional symptoms are generally present.

Treatment.—The general treatment is the same as for boils. Local surgical treatment is required, and consists either of complete excision of the carbuncle, with the surrounding inflammatory tissue, or of making a crucial incision and removing the slough, the open wound being packed with bismuth-iodoform-paraffin paste or an appropriate antiseptic dressing.

SYCOSIS BARBÆ

This is a staphylococcal infection of the hair follicles of the beard region, and is one of the three forms of "barber's rash," the other two being impetigo contagiosa of the beard region and ringworm of the beard.

Ætiology and Pathology.—The disease is produced by inoculation of staphylococci into the hair follicles in the beard area, either primarily or as a secondary infection to an impetigo contagiosa. Many cases doubtless start from infection conveyed in the barber's shop, but a considerable number also occur in patients who shave themselves. Scratches from the razor subsequently inoculated by the patient's finger are probably as common as direct infection from a barber's brush or razor.

Symptoms.—The disease usually begins at one spot in the beard or moustache area by the formation of pustules around the hairs. These pustules tend to occur in groups, and become surrounded by an inflammatory zone. As the deeper parts of the follicles become infected, nodules form and

the whole affected area becomes swollen and œdematous. Pus discharging from the ruptured pustules dries and forms crusts. Subsequently some of the hairs loosen and can be pulled out without pain. Each hair on removal is seen to be surrounded by a swollen and transparent root-sheath, and often a bead of pus escapes from the follicle. The disease is progressive, and eventually the whole beard and moustache area, and not infrequently the eyebrows and eyelashes, may be attacked. It tends to become chronic, and in old-standing cases a large number of the hairs are lost, leaving a smooth, red, atrophied patch, not unlike lupus vulgaris, and to which the name *lupoid sycosis* has been given. The presence of some follicular pustules and the absence of lupus nodules is, however, sufficient to separate the two conditions.

Diagnosis.—In addition to the diagnosis from lupus vulgaris just mentioned, sycosis has to be differentiated from impetigo contagiosa, and from ringworm. From the former the diagnosis is made by the involvement of the deeper structures of the skin and the presence of pus in the hair follicles; from ringworm by the absence of fungus in the scales and hairs (see *Tinea barbæ*, p. 1310).

Treatment.—The acute cases should be treated much in the same way as other acute inflammations of the skin, without any attempt being made directly to attack the organism responsible for the disease. Frequent bathing in warm water or oil should be used to remove crusts, or borie-starch poultices may be used. Lead lotion, or 1 in 1000 acriflavine lotion, should be applied on lint and changed frequently. When the acute stage has subsided the parts should, if possible, be shaved and should be kept shaved, the razor being of the sharpest, and both it and the shaving-brush soaked in 1 in 40 carbolic acid after use. Loose hairs should be epilated and the surface dabbed once a day or more often, if not too painful, with 1 in 1000 biniodide of mercury in 60 per cent. alcohol, and the surface dusted with talc powder. As an adjunct, vaccines may be given. In many cases it is advisable to epilate by X-rays. Provided the inflammation is not too acute, a full Sabouraud pastille dose should be given, and after epilation the area dressed with a 3 per cent. ammoniated mercury ointment.

ANTHRAX INFECTIONS

These lesions, which resemble in some respects those produced by the staphylococcus, are dealt with elsewhere (p. 107).

DIPHThERIA INFECTIONS

The lesions produced by the diphtheria bacillus are rare, but are seen sufficiently often to require notice. Diphtheritic infection of wounds is a well-known condition, but does not need to be considered here. The surface infection by diphtheria is of two kinds; in children suffering from diphtheria, gangrenous patches occasionally develop, chiefly on the trunk, from which cultures of the organism may be obtained, but the organism may also attack the skin of otherwise healthy persons.

Symptoms.—A single lesion usually occurs, but there may be more than one. It begins as a clear blister, like an impetigo vesicle, and ruptures

very easily; on about the second day a considerable red zone is present around the original lesion, and a central slough has formed, comparable to a small burn. This condition persists for some time, if not treated, and eventually the slough separates and the spot heals. Constitutional symptoms may be present. The writer has recently seen a case of paronychia from which a pure culture of the Klebs-Loeffler bacillus was obtained.

Treatment.—Prompt injection of anti-diphtheritic serum, with the application of a local antiseptic dressing, is all that is required.

INFECTIONS BY THE SEBORRHŒIC ORGANISMS

Three organisms are commonly found in cases of seborrhœic dermatitis, but the part each plays is not yet conclusively proved, so that it will be convenient to group the seborrhœic conditions under one heading. The organisms found are the *acne bacillus*, the *bottle bacillus*, and the *Staphylococcus epidermidis albus*. The first named is a small bacillus which is found chiefly after puberty and is present in very large numbers in the comedo of acne vulgaris. The bottle bacillus is a yeast-like organism which buds and often shows itself as a flask-shaped body, and is found most plentifully in seborrhœic dermatitis of the scalp. The white skin staphylococcus is found pretty universally over the skin.

SEBORRHŒIC DERMATITIS

Under this term we include a chronic scaly condition of the scalp, formerly called seborrhœa sicca, and also certain "eczematous" lesions of the face, chest and back, and occasionally on other parts of the body, which are characterised by the presence of more or less circumscribed reddish patches covered by greasy scales.

Ætiology and Pathology.—The histological changes in the skin are those of a chronic superficial dermatitis. The three organisms mentioned above are met with in the scales in all adult cases, but the origin and spread of both seborrhœic dermatitis of the scalp and the figurate type on the body suggest that the views of Sabouraud and Whitfield, that the bottle bacillus is the chief ætiological factor, are correct. Further, the ease with which most lesions clear up under treatment by sulphur supports these views. There is no doubt that an underlying seborrhœa is the main factor in causing the activity of these organisms.

Symptoms.—Seborrhœic dermatitis of the scalp is the well-known "scurfy head," and is an extremely common affection, most individuals having it to a greater or less degree. It probably begins in early infancy, and is sometimes seen as a ringed lesion on the scalp of young infants. These lesions have been shown by Whitfield to contain the bottle bacillus in large numbers. These rings may disappear spontaneously, but the infection, which has presumably been conveyed from the mother or nurse, persists and lights up again later in life in certain individuals, especially in those prone to seborrhœa (see p. 1276). In the adult the affection consists of a diffuse branny scaling on the scalp, usually unassociated with any obvious inflammation of the skin. On close examination the scales are seen to be formed around the hairs, indicating that the inflammation is perifollicular.

Varying degrees of scaliness are met with; in some cases it is scarcely perceptible, in others it consists of thick, greasy masses. Symptoms are generally absent, but occasionally a good deal of irritation is present, which leads to scratching, and small crusted lesions are then found among the scales. Sometimes a more acute inflammation supervenes, and the scalp becomes red and hot, and an exudate of fluid may occur, producing crusting. In these cases the inflammation usually extends for a centimetre or so beyond the hairy margin. The persistence of scaly seborrhœic dermatitis is considered by some to be an ætiological factor in producing that form of baldness known as alopecia prematura, which is characterised by the recession of the hair from the forehead and baldness on the crown of the head. It is probable, however, that other factors also play a part in this condition.

The face may also be affected, especially the eyebrows, forehead, nasolabial folds, beard and mastoid regions. Here the lesions are dry, reddish or pale patches, surmounted by greasy scales or crusts. On close examination it can usually be seen that the lesions are follicular in origin and that the patches are formed by the aggregation of these follicular papules. The ears may be affected, especially the concha, and some forms of blepharitis appear to have a seborrhœic origin. The lesions on the face are very liable to become infected with pus organisms and become thickly crusted. An intractable scaly inflammation of the lips, *cheilitis exfoliativa*, is also considered to be of seborrhœic origin.

On the chest and back ringed or figurate lesions are frequently seen, but here follicular papules may occur. The centre of the sternum and the interscapular area are the common sites. Occasionally patches occur among the pubic hairs.

Some authorities include under this heading cases in which circumscribed pinkish or red circular or oval patches, covered by fine branny scales, occur on the trunk and limbs. They are resistant to treatment, especially to the remedies useful in seborrhœic dermatitis, and there is some evidence that they are forms of the streptococcal dermatitis referred to on p. 1297. This type is prone to attack the flexures of the limbs, as are other streptococcal infections.

Diagnosis.—All cases of scurfy head in children should be considered to be ringworm until careful examination has excluded this cause. The presence of stumps and the demonstration of the fungus will settle the diagnosis. In body ringworm the distribution is irregular, the lesions are sharply circular, and the scaling is not greasy. Fungus can be found in the scales.

Impetigo contagiosa of the small crusted type has a close resemblance to seborrhœic dermatitis, especially on the face. The presence of some definite impetigo vesicles and crusts, and the history of its unilateral spread, may help to clear up the diagnosis.

Pityriasis versicolor occurs in the same regions as the body form of seborrhœic dermatitis, but it has a fawn colour and no inflammatory reaction, and the fungus can be found in the scales. *Pityriasis rosea* can be distinguished by the presence of oval lesions with a collarette of scales within the edge of the lesion, by its acute onset and by its symmetrical distribution.

Prognosis.—The figurate variety on the trunk can always be kept under by appropriate treatment, but frequently recurs. The face is more resistant

to treatment, and when much septic infection has taken place may take a long time to cure. On the scalp constant treatment is necessary, and a permanent cure can scarcely be hoped for, as the organisms invade the follicles. With proper hygiene and appropriate treatment, however, the condition can be kept quiescent.

Treatment.—*Scalp.*—Frequent washing is necessary to remove the scales and accumulated dirt. Unless there is any acute inflammation present, men should wash the scalp two or three times a week or even daily with *sp. sapon. kalin.* (B.P.C.), or *ext. quillaie liq.* (B.P.C.); sulphur or tar soap may be used. In women the washing should be done once a week. After drying, in severe non-inflammatory cases, an ointment containing 3 per cent. each of *ac. salicylic.* and precipitated sulphur in a basis of ʒi soft paraffin and ʒvi coconut oil should be rubbed into the scalp. Resorcin, thymol, anthrasol, thiol or ammoniated mercury 3 per cent. may be used as alternatives or in various combinations. In the milder cases lotions are preferable. Resorcin or chloral hydrate ʒi , *sp. vin. rect.* ʒi , *aquam ad* ʒviij , is a useful lotion. Resorcin should not be used in fair or white-haired patients owing to its staining properties. In the acutely inflamed cases, washing with soap should be avoided, though crusts may be bathed away with warm water. After removal of the crusts, *ichthyol* ʒss in ʒi of *lin. calcis* should be applied, the hair being cut short if necessary.

On the *face*, sulphur and salicylic acid ointment may be used in the chronic cases; if, however, sepsis is present the crusts must be removed and calamine or *ichthyol liniment* applied.

On the *body*, sulphur and salicylic acid ointment is usually all that is required.

ACNE VULGARIS

This condition is characterised by the presence of greasy plugs, known as comedones, in the pilo-sebaceous follicles—particularly those on the face, shoulders, chest and back—often associated with perifollicular inflammation. It is an extremely common affection in its milder forms and by *no means* rare in its severest types.

Ætiology and Pathology.—The disease occurs chiefly in individuals between 15 and 30 years of age, and is seen in both sexes. The affected individuals suffer from *seborrhœa*.

If a comedo is examined it is found to consist of epithelial cells, sebaceous material, and the three organisms which are associated with seborrhœic inflammations and, in addition, a small *acarus*, the *demodex folliculorum*, is sometimes found. In the greater mass of the comedo, the *acne bacillus* occurs almost pure, the other organisms being found chiefly near the mouth of the follicle. Accumulated evidence seems to show that the *acne bacillus* is the chief exciting cause of the comedo, but that secondary suppuration is chiefly due to the activity of *staphylococci*, though this has recently been denied by Sabouraud. The bottle bacillus and the *demodex* appear to play no active part in the production of the disease. The excessive oily secretion of the skin, with the patulousness of the follicles which accompanies this condition (the so-called “*kerose*” of Darier), appears to offer a field for the activities of the *acne bacillus*, which flourishes in the sebaceous secretion.

The actual comedo is formed by exfoliated epithelial cells—produced by an inflammatory hyperkeratosis of the follicle—mixed with sebum.

Symptoms.—The earliest lesions are the comedones or “blackheads.” These are small, black spots which are seen filling the dilated orifices of the pilo-sebaceous follicles, most frequently on the face, but also in the other sites mentioned above. If pressure is exerted on a follicle, a cocoon-like plug can be squeezed out, which is of a cream colour, except for the portion which fills the mouth of the follicle, where it is black. Isolated comedones are extremely common, but when large numbers of them occur the term *acne punctata* is applied to the condition. Frequently, however, the presence of these follicular plugs predisposes to an acute perifollicular inflammation, and the comedo becomes surrounded by a red zone; later, a small pustule may occur in the centre. This lesion is generally painful. When these inflammatory lesions predominate, we speak of the case as one of *acne papulosa*, or *pustulosa*; but it must be noted that all varieties tend to be present together. In some cases the inflammation does not start superficially around the follicular orifice, but deeper, in the region of the sebaceous gland. Here we find first a deep-seated lentil- or pea-sized nodule, often painful, which gradually increases in size, reddening the skin as it pushes upwards, and then sometimes bursts at once and discharges a small quantity of turbid yellow fluid with the remains of the comedo; or it may attain the size of a filbert, and present signs very similar to those of a sebaceous cyst. Sometimes the nodules disappear without rupturing. This type is usually spoken of as *acne nodularis*, and is particularly liable to appear on the back. It is the most persistent type, and often leads to much keloidal scarring.

Diagnosis.—Rosacea, especially the acneiform type, when it occurs in young people may sometimes be mistaken for acne vulgaris, and indeed the two conditions may occur together. In rosacea, vascular congestion is the prominent symptom; the lesions are generally localised to the centre of the forehead, the nose and central portion of the cheeks and the chin—they are painless and the comedo is absent.

Acneiform lesions produced by the internal administration of bromides and iodides may simply be an exaggeration of a pre-existing acne vulgaris; but if not, the lesions tend to be more grouped and to produce tumour-like swellings. Other eruptions characteristic of these drugs may also be present. The acne produced by the irritation of tar and paraffin is usually localised to the forearms and lower limbs.

Prognosis.—The condition tends to die out between the ages of 25 to 30; but the nodular type may often continue till a considerably greater age. Though improvement is sometimes slow, treatment materially hastens a cure. Bad scarring is sometimes left in severe cases.

Treatment.—As the causative organism is situated deeply in the follicle, it cannot be reached by the ordinary anti-parasitic remedies. Treatment must, therefore, be directed to emptying the follicles. In the mildest cases this is best done by frequent washing with spirit soap and hot water, or by steaming. The comedones are then expressed either by a comedo extractor or by pressure with the finger protected by a handkerchief or soft towel. After this a mild sulphur preparation, such as calamine lotion containing 2 per cent. or 3 per cent. of potass. sulphurata or sublimed sulphur should be dabbed on, or if this dries the skin too much 3 per cent. precipitated

sulphur in ung. aquæ rosæ may be used. Ointments, however, should be avoided as far as possible, as they tend to block up the follicles. This treatment must be persisted in for a considerable period. More drastic treatment consists in exfoliating the skin with a resorcin paste.

Vaccines have not given very satisfactory results, though staphylococcal or mixed acne and staphylococcal vaccines have been of some value in the pustular cases.

Of recent years the most rapid cures have been effected by means of X-rays. It must be remembered, however, that atrophy and telangiectasis sometimes occur many years after quite ordinary doses, and although this risk may be taken with impunity on the back, and, in men, on the chest, it is only in the worst cases that it should be used on the face and, in women, on the chest. For the back and chest it is best to give a full pastille dose at a sitting, $\frac{1}{2}$ mm. aluminium filter being used. On the face three $\frac{1}{3}$ rd pastille doses, at 7 to 10 days' interval, will usually suffice, and a fourth dose can be given later if necessary; but it is well to wait at least 6 weeks before deciding on further treatment.

In addition to local treatment the patient's general health must be attended to, constipation rectified, and such conditions as dyspepsia, anæmia and menstrual disturbances treated.

ACNE VARIOLIFORMIS

Synonym.—Acne Necrotica.

An inflammatory condition of the hair follicles, accompanied by local necrosis, and leaving pitted scars resembling those seen in variola.

Ætiology and Pathology.—The disease is seen chiefly in middle-aged persons of both sexes. It is believed to be of bacterial origin, and is attributed by Sabouraud to the acne bacillus. It occurs in seborrhœic individuals.

Symptoms.—The affection occurs chiefly on the scalp and forehead, but is occasionally seen on the face, neck, chest and back. The lesions usually come out a few at a time, and the attacks may persist for long periods; but there are generally intervals of complete freedom. Often change of residence has the effect of stopping or determining an attack.

The lesions at the commencement are pinhead-sized vesicles situated at the mouth of the hair follicles. These vesicles rapidly dry up without bursting, and scabs are formed. These are seen to be depressed below the surrounding skin. When the scabs fall off after a week or so a small punched-out scar remains. The onset is usually accompanied by a good deal of itching or burning.

Diagnosis.—The condition has to be distinguished from the scattered crusts which occur in seborrhœic dermatitis of the scalp as a result of scratching. The diagnosis can be made by the pre-existing vesicular lesions in the case of acne varioliformis, and by the scarring left.

Treatment.—These cases are often resistant to treatment. The general health should be attended to, and often change of air is very beneficial. Local anti-seborrhœic remedies should be applied, such as salicylic acid and sulphur ointment (3 per cent.), ammoniated mercury ointment (10 per cent.), or lotions of potass. sulphurat. and zinc sulphate.

ACNE KELOID

A hypertrophic inflammatory condition occurring on the back of the neck just below the hair margin.

Ætiology and Pathology.—The disease occurs in young adult males. Very little is known of the cause. It occurs at a point where the collar rubs the back of the neck, and friction appears to play a part in its production. The condition has been studied closely by Adamson, who can find no evidence of previous comedo formation. Though he considers that it is produced by a combination of trauma and bacterial infection, he does not consider that the acne bacillus or the *Staphylococcus pyogenes* plays any part in its formation.

Symptoms.—The condition commences with small firm nodules, which gradually increase in size and eventually merge into one continuous mass, closely simulating a keloid.

Treatment.—Adamson recommends large doses of X-rays as the only satisfactory method of treatment.

DERMATITIS DUE TO FUNGI

RINGWORM

Ætiology and Pathology.—Tinea or ringworm is the name given to certain inflammatory affections of the skin produced by the growth in it of certain of the hyphomycetes or moulds. These fungi grow for the most part in the horny layer of the epidermis or its appendages, the hairs or nails, and by their growth produce an inflammatory reaction. The fungi which are commonly seen in this country belong, according to Castellani and Chalmers, to four genera—the *microsporon*, the *trichophyton*, the *ectotrichophyton*, and the *epidermophyton*, the latter of which is characterised clinically by not attacking the hairs. To these must be added a fifth, which though of the same family is not usually included under the term "ringworm," namely *farus*, the fungus of which belongs to the genus *Achorion*. The fungus of ringworm is transmitted to man either from another human being or from certain animals, some fungi being only found in man. The types which are common in one country are not necessarily so in another, and in tropical zones a very large variety occur which are not considered here, but are dealt with fully in works on tropical medicine. The *microsporon*, or small spored ringworm, attacks almost entirely children under the age of about 16, while the *epidermophyton* is not frequently seen in children. The *trichophyton*, however, attacks children and adults indiscriminately. The genera can usually be distinguished without difficulty from one another both clinically and by examining the hair or scales under the microscope in liq. potassæ. The different species can, however, only be distinguished by their cultural characteristics. The same ringworm fungus grows differently on different media, and in order to compare cultures the fungus is by tacit agreement grown on what is known as Sabouraud's "proot medium," for the reason that this observer has collected and illustrated in his book, *Les Teignes*, a very large number of the known ringworm fungi. The common nomenclature of the fungi is that adopted in this work.

Ringworm is found chiefly on the scalp, where it almost universally travels along the hairs into the hair follicles, on the beard region, where the hairs are often but not always affected, or on the glabrous skin, where it usually remains confined to the surface horny layer. The nails are also sometimes attacked.

RINGWORM OF THE SCALP

Ætiology and Pathology.—Ringworm of the scalp, *linea tonsurans*, is essentially a disease of childhood, the adult scalp being so rarely attacked as to be considered a curiosity. In this country about 90 per cent. of cases of scalp ringworm are produced by the microsporon fungus, the large majority of these being produced by a human species, *Microsporon audouini*, the rest (not more than about 5 per cent.) by the microspora of the cat, dog and sometimes other animals. Another 10 per cent. or so of cases are due to trichophyton (or endothrix) and ectotrichophyton (or ectothrix) fungi of each of which there are several species. The microsporon fungus first attacks the horny layer on the surface of the scalp; it reaches the hair shaft at the mouth of the follicle and grows down on and beneath the cuticle of the hair, destroying the cuticle and fibrillating the hair, and finally terminates in a fringe of mycelial processes just above the expansion of the bulb of the hair. The mycelial processes on the surface of the hair break up into small round spores, which are packed so closely together that, when examined in liq. potassæ under a $\frac{1}{8}$ -inch objective, they are seen to form a thick mosaic sheath round the hair. As a result of the damage produced, the hairs first lose their elasticity and then fracture. This fracture usually takes place about $\frac{1}{8}$ -inch above the mouth of the follicle.

Symptoms.—*Microsporon ringworm.*—In the bulk of cases the disease begins with a small circular scaly patch on the scalp. Very soon the hair on the patch is noticed to be thinning. Several patches may appear simultaneously. On close examination with a lens, these circular patches are found to be covered with fine, branny scales of a greyish colour, the follicles are prominent, giving the patches a nutmeg-grater-like appearance, and numerous broken hairs are seen. At the edge some hairs may be found unbroken but bent at sharp angles, as though a sort of greenstick fracture had occurred. These hairs and the stumps are often covered with a whitish powder, which is the spore sheath referred to above.

On pulling one of the stumps with forceps the former will come away, but usually breaks off above the hair bulb, leaving the latter behind; a great deal of perseverance is necessary to remove the stump intact. The hair thus removed and examined in liq. potass. has the appearances mentioned above, and in addition the fibrillation of the hair will be noted, especially the irregular fracture of the distal end. In old-standing cases the regular circular outline of the patches may be lost, the whole scalp having a moth-eaten appearance, and stumps being scattered irregularly over large areas. The microsporon ringworms contracted from animals have similar appearances.

Endothrix ringworm.—The fungus of this type is not contracted from animals. The clinical appearances may be similar to microsporon ringworm, but two other types are seen. In some cases no patches are present, but a general thick scurfiness of the scalp occurs. On very careful search with a

lens isolated stumps may be found scattered all over the scalp. In other cases sharply defined bald patches occur, which on inspection show no stumps, but every follicular opening is filled with a small black spot. By the careful use of pointed epilation forceps, such as those devised by Whitfield, one or more of these spots may be removed, and on examination the fungus can be demonstrated. This type is called *black-dot ringworm*, and has to be distinguished from alopecia areata.

When the stumps from an endothrix ringworm are examined in liq. potass. under the microscope the spore sheath is found to be absent, the fungus being entirely inside the hair and the cuticle intact. The fungus itself consists of longitudinally running mycelial filaments, which are divided up into small square, round or oval segments, which are called spores, the whole having a ladder- or chain-like appearance.

Ectothrix ringworm.—The fungus which produces this type is of animal origin, and generally produces a much more inflammatory type of lesion than the other varieties. In the majority of cases suppuration occurs, the fungus itself being responsible for pus formation. These suppurating ringworms are spoken of as *kerion celsi*. The affected area is much swollen and red, and often raised considerably from the surrounding skin. The swelling is boggy to the touch, and often gives the sensation of fluctuation, which to the uninitiated suggests abscess formation. On the surface pus is seen to exude from numerous follicular openings, but broken hairs are also seen. These if examined in liq. potass. show fungus, both within and without the hair: the cuticle is destroyed and the mycelium has similar characters to the endothrix fungus, the spores being arranged in chains and not packed together, as in the microsporon type.

Diagnosis.—This is usually simple, the presence of the stumps containing fungus being diagnostic. In cases where stumps are few in number, great help can be obtained by examining the child's scalp under a mercury-vapour lamp, screened by what is known as "Wood's glass." The affected stumps fluoresce brilliantly and can be readily seen. This method is particularly valuable in determining whether a case is cured after treatment. From favus the diagnosis is made by the presence of yellow favus cups. From seborrhœic dermatitis the diagnosis should not be difficult if it is always remembered that a scurfy head in a child must always be considered to be ringworm until this has been excluded. Great care has, however, to be taken to make a thorough search for stumps in the endothrix cases. In alopecia areata a smooth, shiny centre with, perhaps, a row of scattered stumps at the periphery of the patch is found. These stumps, however, are club-shaped, are very thin as they enter the scalp, and when pulled out always come away with a shrunken bulb attached. No fungus can be seen on microscopic examination.

Treatment.—The cardinal fact to remember in the treatment of scalp ringworm is that up to the present no means has been discovered of killing the fungus in the hair follicles. It is, therefore, necessary to epilate the hairs in order to obtain a cure. This can be done by three methods: by X-rays; by producing sufficient inflammation in the affected areas to make the hairs fall out; or by the administration of thallium acetate internally. This second method is the way Nature cures some cases. In kerion the suppuration is sufficient to loosen the hairs, and all that is necessary is to assist this process

by hot fomentations and epilation with forceps. In the ordinary microsporon type, however, the production of the necessary inflammatory reaction is not so easy. Various irritants have been used—the most satisfactory of which is croton oil. The application of this, however, requires great care, and is not suitable for ordinary out-patient practice. Probably the best application available at present is an ointment of equal parts of common salt and soft paraffin. The scalp is shaved and washed daily with soap and water, the healthy portion then smeared with a weak mercurial ointment, such as 2·5 per cent. white precipitate ointment, and the salt ointment rubbed vigorously into the ringworm patches. After a time the patches inflame, and the hairs loosen and fall out. Cure by this method in fairly localised cases takes 2 or 3 months if the treatment is vigorously and conscientiously carried out; otherwise it may take 12 or 18 months to effect a cure. In out-patient practice, and in all extensive cases, X-rays are preferable. The method used is that devised by Adamson and Kienboeck, and consists in treating the scalp from five different points with a Sabouraud pastille dose, the points being so arranged that the whole scalp is uniformly irradiated. This should cause all the hair to fall out in 3 to 4 weeks, and a complete cure should take place. There is a risk of permanent alopecia occurring even under the most careful arrangements, but it is very slight; it is well, however, that parents should be fully informed of this risk before the treatment is commenced, in order to avoid any subsequent unpleasantness.

It has recently been shown, chiefly owing to the work of Buschke and his associates, that, if thallium acetate in a single dose of 8 mgrms. per kilo body weight be administered orally, the scalp hair will fall out after about 18 days, leaving the eyebrows and eyelashes unaffected. This method has now been used in a large number of cases of ringworm, and gives satisfactory results. It does, however, often produce well-marked toxic symptoms, chiefly severe joint pains and gastro-intestinal disturbance, and its final beneficial results are probably not equal to those of X-rays. It should only be given to children who are perfectly healthy.

RINGWORM OF THE BEARD

Symptoms.—Ringworm of the beard, *linea barbæ*, occurs in two types: (1) the superficial, scaly type, and (2) the suppurative type. The former begins as a small scurfy patch, which spreads slowly in ring fashion, and resembles the scaly type on the scalp. The hairs are usually attacked, and if removed fungus can be demonstrated in them and also in the scales. The fungus is usually of the endothrix type, and as such is transmitted from man to man. It is not infrequently caught in the barber's shop, and is one of the three forms of "barber's rash."

The suppurative type produces an irregular lumpy swelling of the affected part. The "lumps" are soft and boggy to the feel, and pus may be seen exuding from various follicular openings; the case bears a close resemblance to kerion celsi, but has not the same sharp circular edge, being more irregularly distributed. The hairs are attacked by the fungus, which in this case is generally of the ectothrix type, and is usually transmitted from animals, being frequent among grooms and cattlemen.

Diagnosis.—The scaly variety must be distinguished from seborrhœic

dermatitis and the pityriasiform type of streptococcal infection. This is easily done by the presence of fungus in the hairs and scales of ringworm.

The suppurative type may be confused with the staphylococcal sycosis; but the latter never forms the tumour-like masses which are seen in ringworm, while again the presence of fungus will settle the diagnosis.

Treatment.—The same principles apply as in scalp ringworm. For the scaly type X-rays form the most certain form of treatment; but the risk of atrophy must not be forgotten. If patients decline to take this risk 3 per cent. salicylic and 5 per cent. benzoic acid ointment should be rubbed in daily and the hairs epilated, a few at a time, with forceps. The hair should be kept cut short.

With the suppurative variety hot fomentations and epilation with forceps should be used.

RINGWORM OF THE GLABROUS SKIN

This can be divided into four types. (1) *Tinea circinata*, the small ring- and disk-like patches seen about the face, neck, body and limbs; (2) *tinea cruris*, *eczema marginatum* or *dhobie itch*, seen chiefly as sheet-like patches in the inner side of the thighs, and on the perineum and scrotum; (3) the *eczema-toid ringworms* of the hands and feet; and (4) the *pustular body ringworms*.

Symptoms.—1. *Tinea circinata*.—This condition may occur by itself or in combination with scalp ringworm. In the latter condition it usually occurs on the neck or face. In the microsporon cases of human origin the lesions take the form of small disks, usually not larger than a threepenny bit, which show little tendency to grow, and no tendency to clear in the centre or to form rings. The patches are of a pale pink colour, and are covered with branny scales, in which mycelial filaments can be demonstrated by examining them under a $\frac{1}{4}$ -inch objective in liq. potassæ. The other varieties of microsporon and the endothrix trichophytions show a much greater tendency to form rings and to attain a larger size. In these cases the earliest spots are similar to those described above, but as they spread the centre loses its scaliness, becomes a paler colour, and eventually the skin resumes its normal character. The spreading edge presents the same branny scaling, and often small pinhead-sized vesicles and pustules. As before, mycelial filaments can be demonstrated in the scales. Itching is often present to a greater or less degree. In rare cases these rings are very numerous, and concentric rings may form. This is well seen in some tropical varieties, such as *tinea imbricata*, where the whole body is covered with concentric ring-formations.

2. *Tinea cruris*.—This condition, also known as *dhobie itch*, is produced by the genus *Epidermophyton*. It is so named because of the commonly held view that clothes are infected by the washerman or dhobie. Originally a tropical type, it is now extremely common in this country, being much more often seen in private than in hospital practice, and almost entirely in males. It is usually seen as a superficial, flat, brownish-red patch situated bilaterally on the inner surface of the thighs in their upper third. The patches usually meet on the perineum, and often involve the whole scrotum, and sometimes spread forward into the groins. The patches, which were formerly known as *eczema marginatum*, have a very sharply defined margin, which is very slightly scaly, but no vesicles are present. Scrapings from the scales show

a chain-like mycelium. The patches, though usually confined to this region, are occasionally seen on the umbilicus and in the axillæ, and are frequently associated with one type of eczematoid ringworm seen between the toes. There is generally intense itching felt in the patches.

3. *Eczematoid ringworms*.—There are several varieties of this type seen. The commonest is that which occurs between the toes, and generally accompanies the type just described. It occurs first between the little and fourth toe, and is generally bilateral. The skin in the web of the toe becomes thickened, whitish and sodden, and fissuring is prone to occur. It may spread to adjoining interdigital spaces, and on to the dorsum and sole of the foot. In severe cases a raw red weeping area, bounded by a sharp margin, is produced. It is not always easy to demonstrate the fungus in the thickened skin between the toes; considerable time must be given to soaking in liq. potassæ the skin removed, and many slides may have to be made before the search is rewarded. This type has been described on the hands, but is very rare.

The most common type seen on the hands consists of rather sharply circumscribed patches of a vesicular dermatitis. They may occur on any part of the hand or fingers, and are generally single and unilateral. They spread slowly, and are itchy. The lesions are usually produced by the endothrix fungus; but others may be found. The demonstration of the fungus is necessary to distinguish them from other forms of localised dermatitis. When the lesions occur on the palm much thickening of the horny layer is produced, and cracking in the deeper folds may take place.

In another form an acute dermatitis, which may involve both hands and feet, is set up, as has been shown by Whitfield. The cases are clinically indistinguishable from the type of acute dermatitis known as dysidrosis or cheiropompholyx, and in all such cases a careful examination must be made for a ringworm fungus.

4. *Pustular body ringworms*.—These occur in sharply defined patches, chiefly on the limbs and neck. The patches are of dull red colour, and sharply raised from the surrounding skin; they have a soft boggy feel, and pus can be seen exuding from the follicles. The fungus in this case is usually of the ectothrix variety.

Diagnosis.—This is only difficult in the acute eczematoid varieties, when it must be distinguished from cheiropompholyx and the localised forms of dermatitis and eczema. This can only be done with certainty by demonstrating the fungus. The circinate patches have to be distinguished from seborrhœic dermatitis and the scaly streptococcal lesions, and on the face from pityriasis simplex. The presence of fungus, and the ease with which patches respond to Whitfield's ointment, as well as the tendency to ring-formation, and asymmetrical distribution, will enable a diagnosis of ringworm to be made.

Treatment.—This is simple in the flat body patches and in tinea cruris. Many antiseptics, such as iodine, sulphurous acid and chrysarobin, will clear up the patches, but the simplest and most easily applied agent is Whitfield's ointment, which consists of 3 per cent. of salicylic acid and 5 per cent. of benzoic acid in a paraffin or paraffin and cocoa-nut oil basis. Most patches will clear up in a week if the ointment be rubbed in once or twice a day; but it is well to continue the application for some days after the patches have subsided, especially in tinea cruris.

Eczematoid ringworm of the toes can be treated with a double strength ointment of the same constituents, the sodden epidermis being removed daily after washing with soap and water; it is well to use this intermittently for 2 weeks at a time, powdering the toes well with a bland powder during the alternate 2 weeks, in order that the keratolytic action of the salicylic acid may subside and give a better indication of the results of treatment. In resistant cases 20 per cent. chrysarobin in spirit may be used in addition. These cases are always resistant to treatment, which requires to be carried on for long periods.

The acute eczematoid ringworms of the hands are often made worse by strong parasitocides, and it is generally better to start treatment with a wet dressing of 1 in 4000 potassium permanganate, subsequently trying small areas tentatively with the stronger ointments. The suppurative type can also be treated with 1 in 1000 acriflavine, or 1 in 4000 perchloride of mercury dressing, and subsequently with Whitfield's ointment, if not cured by the former methods. Resistant cases respond well to X-ray treatment.

RINGWORM OF THE NAILS

This is fortunately not a very common affection, but occurs with sufficient frequency to be on the look out for. It may be caused by the endothrix or ectothrix fungus.

Symptoms.—Usually 2 or 3 nails are affected, nearly always those of the fingers—the toe nails being very rarely attacked. The disease usually commences under the free end of the nail, and travels slowly upwards. The nail bed becomes much thickened, and the epithelium sodden, and can be scraped away. As the disease spreads the nail becomes a greenish-grey colour and separated from its bed; the growing edge can be seen as a yellowish line above the discoloured and separated nail. In other cases the nail becomes soft or brittle and breaks up, exposing the underlying sodden nail bed. Very rarely the sides and base of the nail may be primarily affected.

Diagnosis.—The diagnosis has to be made from eczema, psoriasis and syphilis. This can only be done with certainty by finding the fungus. Portions of nail near the growing edge should be taken and soaked for some hours in liq. potassæ. The under surface is then scraped and mounted, and a search made; and this may require several preparations before the mycelium is found. Cultures can often be made direct from pieces of nail; but contamination is very frequent.

Treatment.—The nail must be removed, either surgically or by softening in strong potash and scraping it away. Afterwards one of the stronger anti-trichophytic remedies can be applied. Norman Walker recommends covering the affected nails with lint soaked in Fehling's solution and applying a rubber finger-stall for 24 hours or longer, so as to remove the nail completely. The solution must not be applied to the surrounding skin.

OIDIOMYCOSIS

A good deal of attention has recently been paid to lesions closely resembling those produced by the ringworm fungi, but attributable to the growth of yeast-like organisms resembling those found in thrush. The lesions are

chiefly found in moist situations, such as the groins, under the breasts and between the toes. The same fungus has been found to be responsible for a sodden condition between the fingers, to which the name *erosio blastomycetica interdigitalis* had formerly been applied. It has also been found in the nail folds, producing a curious bolster-like swelling of these structures, and has also attacked the nails themselves.

The *treatment* of these conditions is similar to that employed in ringworm.

FAVUS

Favus is a disease due to the growth of a fungus allied to ringworm, belonging to the genus *Achorion*. It differs from the former in forming thick, yellow, circular cups which cause local scarring and atrophy of the hair follicles. It is a much rarer disease in this country than formerly; but cases are still occasionally seen.

Symptoms.—Favus attacks the *scalp*, the glabrous skin and the nails, and has been recorded on the mucous membranes. On the scalp it appears as a collection of pea-sized or slightly larger circular yellowish crusts standing up from the skin and having a central depression, through the centre of which the hair projects. This is the favus cup or scutulum. Very large areas of the scalp may be involved in the process, the whole having a honey-combed appearance. Where the disease has been cured, scars and permanent alopecia are left. In section the yellow cup is seen to be made up of masses of mycelium radiating from the centre. Favus on the *glabrous skin* shows a somewhat similar appearance, a collection of bright yellow cups forming a massive crust, the whole being surrounded by an inflammatory zone. When seen in this country the lesions are generally very few in number and on the exposed parts, but in some countries where the disease is common the whole body may be covered with great masses of favus scutula. Favus of the glabrous skin in this country is often of mouse origin, and a different species to the scalp favus. Favus of the *nails* has somewhat similar characteristics to that of ringworm of the nails.

Treatment.—The only satisfactory treatment for favus of the *scalp* is X-rays. The risks of alopecia mentioned in the treatment of ringworm need not be considered here, as alopecia will result in any case from the disease. As a preliminary to X-ray treatment the crusts should be removed and the scalp cleaned up with appropriate antiseptic applications.

In *body* favus the scutula must be removed, and the patches treated with either Whitfield's salicylic and benzoic ointment or a 10 per cent. chrysarobin ointment.

Favus of the *nails* is treated in the same way as ringworm of those parts.

TINEA VERSICOLOR

This is a superficial infection of the horny layer with the *Microsporon furfur*, and is frequently seen among hospital out-patients.

* **Symptoms.**—It usually forms very thin, greenish-yellow patches or a continuous sheet over the chest and abdomen; but may cover larger areas of the body. It is said to occur chiefly in people who wear thick woollen underclothing and perspire freely. If the patches are scraped scales can be

removed, and these examined in liq. potassæ show thin mycelial threads with large round spores among them.

Treatment.—The treatment is the same as for other body ringworms, salicylic and benzoic acid ointment or a sulphurous acid lotion causing rapid cure. The underclothing should, however, be sterilised, or reinfection will occur. Precautions against over-clothing should also be taken.

ERYTHRASMA

This is an uncommon disease in this country, and is due to the infection of the horny layer with an extremely small fungus, the *Microsporon minutissimum*.

Symptoms.—The affection occurs as superficial, reddish-yellow patches and plaques, more or less symmetrically arranged, chiefly in the groins and axillæ.

Diagnosis.—The malady is to be distinguished chiefly from tinea cruris, and this can readily be done by noting the size of the mycelial elements under the microscope. In erythrasma they are so small as to require a $\frac{1}{2}$ -inch objective, and under it appear as small bead-like chains, with masses of spores intermingled, while in tinea cruris chain-like mycelium can easily be seen under a $\frac{1}{8}$ -inch objective.

Treatment.—The treatment is the same as for pityriasis versicolor.

LEPOTHRIX

This is a not very uncommon affection of the axillary hairs in which they become surrounded with dark reddish concretions.

According to Castellani, this affection is caused by a bacillary-like fungus, *nocardia tenuis*, acting in symbiosis with a red pigment-forming coccus, *micrococcus castellanii*.

The treatment consists in dabbing the affected hairs twice daily with alcoholic formalin (2 per cent.), and rubbing in at night a 2 to 5 per cent. sulphur ointment. Calamine lotion may be used to allay any irritation caused by the treatment (Castellani).

DERMATITIS DUE TO ANIMAL PARASITES

The affections of the skin due to animal parasites are of a mixed variety, but for general purposes may be classed under the superficial dermatoses. Animal parasites produce their effects on the skin either by puncturing and injecting an irritating substance or by burrowing in the skin; but what have chiefly to be taken into consideration are the secondary effects produced by the irritation these creatures produce. In tropical countries the number of animal parasites which produce skin lesions is very large; it is proposed here, however, to consider only those seen commonly in this country.

BITES AND STINGS

The common flea, the bed-bug, gnats and the pediculus family are the common biting insects seen in this country, while of the stinging insects

bees, wasps, hornets and ants may be mentioned. Excluding pediculi, which require more detailed description, the lesions produced by all these insects are wheals of varying size, depending on the particular insect, and also on the susceptibility of the person attacked. The lesions are familiar to all, and require no detailed description.

Treatment.—As most of these stings are due to an acid irritant, the application of weak solution of ammonia and other alkalis gives most relief. In the case of the bee the sting should be removed if still in the skin.

PEDICULOSIS

Three forms of pediculi attack man: the *Pediculus capitis*, the *P. vestimentorum* or *corporis*, and the *Pediculus* or *Phthirius pubis*.

The first two are merely varieties of the same species—the *Pediculus humanus linnaeus*.

PEDICULOSIS CAPITIS.—**Ætiology.**—This condition is caused by a small insect, 2.5 to 3 mm. long, with an oval body consisting of a narrow thorax and wide abdomen, to the former of which are attached six legs, each being provided with a hook-like extremity, with which it hangs on to the hairs. The head is small, oval and provided with two antennæ, a powerful mandible and a proboscis, with which it punctures the skin in order to suck the host's blood. This variety is found among the scalp hairs, chiefly in female children of the lower classes. Pediculi breed with great rapidity, laying their eggs on the hairs. The eggs are contained in a chitinous, ovoid cell, with a movable lid or operculum, and are known as nits; they are laid from the scalp outwards, and each is stuck on to the hair by a drop of cement extruded by the female as she moves along the hair. Nits can only be removed by unthreading them from the hairs.

Symptoms.—Itching is the only symptom produced by the *P. capitis*, and this is due to an irritating substance injected by the insect when it bites. A large number of infested individuals feel no itching; they are, however, a source of danger, as they infect others. If the itching is severe, scratching follows, and this frequently causes impetigo contagiosa, which is most marked at the back of the scalp, but may spread to the vertex, eventually involving the whole scalp and matting the hair down among thick crusts. Similarly it may spread to the back of the neck and shoulders, and involve large areas of the body. Even when impetigo is absent, the presence of scratch marks on the back of the neck and shoulders is almost diagnostic of *P. capitis*.

Diagnosis.—All cases of impetigo of the scalp, especially in children, should be examined for pediculi. The diagnosis is easily made by finding the pinhead-sized, white, shiny oval bodies attached to the base of the hairs, and in bad cases the transparent little insects themselves can be seen scuttling about among the hairs.

Treatment.—The insects are easy to kill, but the nits are more resistant. The favourite method is to saturate the scalp with paraffin and tie it up for 12 hours; this has the disadvantage of being messy, and is not free from danger if the head is brought too near a naked light. Whitfield's method of saturating the hair with 1 in 40 carbolic acid and then tying the hair up in it for half an hour is very efficacious, especially when much impetigo

is present. After this, the crusts can be removed and the nits combed out, and a weak ammoniated mercury ointment applied.

PEDICULOSIS VESTIMENTORUM.—**Ætiology.**—The causative parasite has exactly the same anatomical character as the preceding, but is usually slightly larger, up to 3 to 4 mm. in length. It is not very common in civil life, being only seen in the habitués of the casual ward and the common lodging-house. In war-time, however, it becomes one of the chief causes of sick wastage of armies, being almost universal in its incidence and causing an enormous amount of skin disease.

The insect lives chiefly in the clothes, coming on to the body in order to feed; it is chiefly found, therefore, in those parts of the clothing which come into most intimate contact with the body. In civil life the *Pediculus vestimentorum* is rarely seen, but its nits may be found in the seams of the under-clothing of infected persons. Occasionally in heavily infested people nits may be found on the axillary, pubic and perineal hairs.

Symptoms.—The skin lesions in this condition are mainly those produced by scratching. Closely placed, small, red macules may occasionally be seen, the results of the insect bites, but this is unusual. The scratch eruption has a characteristic distribution and type. In civilians, it is most marked about the back of the shoulders and around the waist and upper part of the buttocks. In soldiers, it is even better marked on the legs and about the knees, owing to wearing the puttee. The lesions in earlier cases are papules, surmounted by hæmorrhagic crusts and linear excoriations. In cases of longer standing, areas of eczematization and lichenification occur, and the skin becomes irregularly pigmented. Septic complications are not very common in civil life, but in the field are the rule. Boils and linear, gutter-shaped ulcers, described under ecthyma on p. 1297, are extremely common under these latter conditions, chiefly on the legs.

Diagnosis.—This has chiefly to be made from scabies, but the presence of the burrows and the distribution of the rash—described in detail in the article on that disease (p. 1318)—should enable a diagnosis to be made. From senile pruritus the diagnosis can only be made by finding lice or their nits.

Treatment.—Disinfection of the clothing and bedding of the infected person is all that is required, except in those who harbour nits on their hairs, in which case the latter should be cut short or shaved. Most local sanitary authorities will carry out the necessary disinfection if duly notified; the methods employed scarcely come within the scope of this work. Local lesions can afterwards be treated with sedative lotions and creams, and impetiginous lesions as already described (p. 1296).

PEDICULOSIS PUBIS.—**Ætiology.**—The *Pediculus* or *Phthirus pubis* has a different appearance from that of the above-mentioned varieties; the body is shorter, wider and almost triangular in shape. It is usually about 1.5 mm. long and about the same width, and is provided with six legs, which are more curved than in *Pediculus humanus* and are also provided with hook-like extremities. This louse can move with considerable rapidity along the hairs, but has very limited powers of movement on a flat surface. When found among the hairs it is seen clinging with its legs to two adjacent hairs. Its eggs are laid in the same manner as with other varieties.

The pubic louse is found almost exclusively in the pubic and perineal

hair, but in severe cases the hair in front of the abdomen, chest and thighs may be infested, as may also the axillary hairs, the beard, the eyebrows and eyelashes. It is extremely rare on the scalp. It is usually transmitted during coitus.

Symptoms.—There are two main symptoms, itching and the presence of small bluish stains on the skin. The itching is often intense and may lead to loss of sleep, but is localised to the area attacked. Scratch lesions are not very common, doubtless owing to the protection afforded by the stout pubic hairs; they do, however, occur. The bluish stains found on the skin in regions infested by the crab-louse are now known to be produced by the bites of the insect. They are 4 to 10 mm. in diameter, not raised above the skin, and do not disappear on pressure. They are known as *maculæ cæruleæ*.

Diagnosis.—This is made by finding the louse and its nits attached to the base of the hairs.

Treatment.—The best results are obtained by clipping the hair short and rubbing in 1 per cent. β -naphthol ointment. Ung. hydrarg., carbolic acid lotion (1 in 40), and petrol are also used, but the former of these may set up a severe dermatitis if not carefully used. On the eyelashes, the insects and their nits should be removed with forceps.

SCABIES

Ætiology.—Scabies is a disease caused by a spider-like, acarine parasite, the *Sarcoptes scabiei*. The acari form a large group of animal parasites which attack man and the lower animals. The parasite generally found in man (var. *hominis*) is a special variety and is not contracted from animals. Various other acari, however, which attack animals may also attack man, but they do not produce identical symptoms.

The *Sarcoptes scabiei*, commonly spoken of as the acarus, is a minute round body, just visible to the naked eye, and of white shining appearance. The body bears eight legs, which differ in the two sexes. In both sexes the two anterior pairs bear suckers; in the male the third pair bear long bristles and the fourth pair bear suckers, while in the female both hind pairs bear bristles. The female is larger than the male, and burrows in the horny layer of the skin to lay her eggs. If undisturbed the female may live for 2 to 3 weeks and lay up to about 30 eggs. The eggs are laid in the burrow and the young hatch out there, the complete cycle from egg to mature acarus being completed in about 10 days. The larvæ, however, hatch out in 3 to 3½ days.

The female acarus has certain favourite sites for burrowing, namely, the genitals, the fronts of the wrists, the web and sides of the fingers, the ulnar border of the hand, the backs of the elbows, the anterior axillary folds, the nipples in women, the umbilicus, the sides of the gluteal cleft and lower part of buttocks, the front of the knees, the ankles and the dorsum of the feet. In infants the palms and soles are also frequently affected.

Symptoms.—The eruption of scabies is of two kinds—the acarine burrows and the follicular papular eruption. The burrows occupy the sites named above. They are seen most clearly on the hands, where they usually

form thin, sinuous lines, from a millimetre up to a centimetre in length and occasionally even longer. The burrow is generally easily seen, as dirt accumulates in it, but quite often it can only be recognised by a lens. The oldest part of the burrow has a splay mouth, while at the other end the small white body of the acarus, with a black spot in its fore part, can be easily seen with a lens and often with the naked eye. Frequently a clear vesicle or vesicles are seen beneath the burrow, but as a rule on the hands no redness is present unless secondary infection has occurred. When blisters are present, secondary infection is frequent, and pustular, weeping and crusted areas are produced. In other sites vesicles are not common, but a large pea-sized papule usually underlies the burrow, and the burrow itself and its acarus are not so easily seen; these lesions are frequently seen on the penis, scrotum and anterior axillary folds, and are usually diagnostic.

The follicular papular eruption is arranged in smaller or larger circles round the areas where the burrows occur. The main distribution is on the anterior aspect of the body, from the nipples to the knees, and in a semi-circle around the anterior axillary fold. The back is free, except in severe cases, down to the top of the gluteal cleft, but scratch lesions occur on the lower part of the buttocks, where ecthyma is often a complication, and on the back and inner parts of the thighs. On the limbs the eruption occupies both front and back of the forearms, up to about the centre of the arm, and also occurs around the ankles. The lesions are first pinkish or whitish elevations of scattered hair follicles, but soon they become covered with bloodstained crusts from scratching. Linear scratch marks are rare in scabies. It is not clear what produces the scratch eruption in scabies, but the work of J. W. Munro suggests very strongly that the follicular lesions are produced by the acarine larvæ, and the distribution of the lesions adds confirmation to this view.

In old-standing cases almost the whole body may be affected, though the face and scalp are practically never attacked in adults; but in small children even these areas may suffer.

Diagnosis.—In well-marked cases no difficulty arises, as the burrows can be seen, but in treated cases the diagnosis may be very difficult and a diagnosis from pediculosis may have to be made. Also the two conditions may occur together. The distribution and character of the rash will usually settle the point, but a careful search with a lens for burrows and acari should always be made.

Treatment.—This depends more on the carrying out of detail than on the actual parasitocides used. Three things are necessary, namely, the opening of the burrows by scrubbing, the subsequent application of a parasiticide to the body, and the disinfection of clothes and bedding. The body should be soaked in a hot bath, then rubbed with soft soap, and finally scrubbed with a brush, particular attention being paid to areas where burrows occur. After this sulphur ointment (B.P.) is rubbed in all over the body (face and scalp excepted), and the patient again dresses, his clothes having been disinfected in the meanwhile. On the two following days the ointment is again rubbed in, but no bath given (as it tends to increase the liability to sulphur dermatitis), on the fourth day nothing is done, and on the fifth day the patient has a bath—to wash off the ointment—and puts on

clean things, all dirty linen being sent to the wash. If any dermatitis from the sulphur arises, lin. calaminæ, to which 2 per cent. liq. pic. carb. is added, may be smeared on, and if there is much sepsis appropriate treatment can then be applied. Balsam of Peru ointment, 12 per cent., and β -naphthol, 5 per cent., may be used as alternatives to sulphur. Many other methods are in vogue, but the above is generally the most satisfactory.

B.—THE DEEP INFLAMMATORY DERMATOSES

Under this heading are included those inflammatory conditions which start in the dermis or hypoderm, and only involve the epidermis secondarily. It is often easy to decide clinically whether an inflammation starts in the dermis or in the hypoderm, and strictly these conditions should be described separately; but as the same exciting cause may often produce either condition, it is simpler to describe them together.

The causative irritant may reach the point attacked in three ways—namely, (1) through a crack or puncture in the epidermis, (2) by the lymphatics, or (3) by the blood stream. In the first group are included those cases in which certain chemical poisons are introduced into the skin by the bites and stings of insects (already dealt with on p. 1315), and cases in which micro-organisms are introduced into abrasions, as in the case of erysipelas from the streptococcus (p. 55), syphilitic chancre from the *Spirochata pallida* (p. 190), soft sore from Ducrey's bacillus, lupus vulgaris and lupus verrucosus from the tubercle bacillus (p. 1334), and actinomycosis, sporotrichosis, etc., from certain fungi. The second group includes certain lesions produced by bacterial irritants, such as are seen in the lymphangitic abscess in tuberculosis and the sporotrichial gummata. The third group includes the drug eruptions and other dermatoses, which are labelled toxic eruptions and which are presumably due to chemical poisons circulating in the blood, and also eruptions due to the circulation of micro-organisms, such as are seen in the syphilides and tuberculides. For convenience of description it is proposed to deal with the majority of deep inflammatory dermatoses under two headings—(1) the toxic eruptions, and (2) eruptions produced by living organisms. It must be understood, however, that in the present state of knowledge the ætiology of many of those included in the former group is still very obscure. There is also a third group of dermatoses whose characters make it difficult to place them in either group, and these have, therefore, been described as (3) *dermatoses of unknown origin*.

TOXIC ERUPTIONS

It is practically impossible to produce experimentally in animals any of the toxic eruptions, owing to the fact that no animal has a skin comparable to that of man. Consequently, all our experimental knowledge of toxic eruptions has to be derived from the observed effects of drugs and food-stuffs on the human skin. It is, therefore, proposed to consider first the eruptions produced by these substances.

DRUG ERUPTIONS

These fall into two great classes—those produced by protein-containing and those by non-protein-containing drugs. The latter include all the ordinary galenicals, while the former include serums and vaccines, as well as protein food-stuffs. Extracts of organs given by the mouth rarely, if ever, produce eruptions and are, therefore, not specially considered.

NON-PROTEIN-CONTAINING DRUGS.—Two classes of eruption are produced by these—(a) Non-specific eruptions, which may be produced indiscriminately by many different drugs, and (b) specific eruptions, which are peculiar to certain drugs.

Symptoms.—**NON-SPECIFIC ERUPTIONS.**—These are generally erythematous, urticarial or purpuric. The erythematous rashes may be scarlatiniform, morbilliform, or, more rarely, of the erythema multiforme type; sometimes the lesions are vesicular. Urticarial lesions are usually of the simple urticaria type, but occasionally the giant forms are seen. Purpuric lesions are often erythematous at the start and develop hæmorrhages later. It is difficult to classify drugs into any special groups by the reactions they produce, but it may be noted that the under-mentioned types of eruption may be produced by the drugs named:

Erythematous.—Acetanilide, alcohol, antipyrine, arsenic, aspirin, belladonna, benzoic acid, cantharides, capsicum, chloral, chloralamide, chloretone, chloroform, copaiba, cubeba, digitalis, ipecacuanha, mercury, opium, pilocarpine, phenacetin, quinine, rhubarb, salicylic acid and the salicylates, stramonium, strychnine, sulphonal, turpentine and veronal.

Urticarial.—Antimony, arsenic, benzoic acid, chloral, copaiba, digitalis, opium, phenacetin, pilocarpine, quinine, salicylic acid and the salicylates, santalin, turpentine and valerian.

Purpuric.—Arsenic, chloral, chloroform, copaiba, ergot, hyoscyamus, iodoform, mercury, phosphorus, quinine, salicylic acid and the salicylates, stramonium and sulphonal.

SPECIFIC ERUPTIONS.—Certain drugs give rise to eruptions which are characteristic of the drugs. The following are the most important:

Arsenic.—In addition to simple erythematous and urticarial lesions, an acute generalised exfoliative dermatitis may develop. This is especially seen after injections of salvarsan. Herpes zoster also occurs, presumably from the action of arsenic on the posterior root ganglia. Pigmentation, especially about the trunk, though it may be more or less generalised, is seen in chronic arsenical intoxication. It usually presents a fine reticular pattern. Hyperkeratosis occurs chiefly on the palms and soles; it may be diffuse or occur in localised, corn-like projections. Occasionally these localised hyperkeratoses develop into epitheliomata. Excessive sweating of the palms and soles (hyperidrosis) may occur, and the nails may become striated and brittle.

Bromides.—Two main types of specific eruption are seen. Bromide acne is a follicular hyperkeratosis, often closely resembling acne vulgaris and seen in the same situations, but often more extensive, involving the legs and arms, as well as the face, chest and back. It is seen chiefly in epileptics who have taken bromide for some time. The other form is the so-called “anthracoid” form, which is most commonly seen in infants and children;

in the former the drug is often conveyed in the mother's milk. Nodules and tumours varying in size from a pea up to an inch or two in diameter are found, chiefly on the face and legs. The tumours are of a deep red colour and studded with minute pustules; in the larger lesions the surface is often crusted, and in some cases ulceration occurs.

Iodides.—The most typical lesions produced by iodides are papules which look like vesicles and bullæ, but when pricked only blood escapes. They are sometimes spoken of as "pseudo-bullæ." They are common on the face and extremities, and often appear after taking quite small doses of iodides and within a very short time, even as quickly as 24 hours. They are most common in patients suffering from nephritis. These lesions may increase rapidly in size and produce large tumour-like masses, studded with pustules or with a crusted or ulcerated surface, and when occurring in patients who are seriously ill may hasten a fatal termination from septic absorption. In the early stages the cases have been mistaken for small-pox. An acne similar to that produced by bromides is also seen.

Antipyrine.—In addition to producing the more generalised types of eruption, antipyrine may produce large erythematous reddish or purplish patches, situated discretely over the body, of sharply circular outline and giving rise to a sensation of burning. When they subside they leave a very marked pigmentation, which disappears very slowly.

Phenol-phthalein.—This drug, now largely used as an aperient and contained in many proprietary remedies, occasionally produces an eruption similar to the last named. The patches are of dull purplish colour and come out on face and limbs, but often also affect the mucous membrane of the mouth. The lesions belong to the group known as "fixed eruptions," as they tend to recur at the same site if the drug is repeated.

Mercury.—This drug occasionally gives rise to a severe erythema in the groins and axillæ, and also on the palms and soles. There may be also purpuric spots and vesicles. Other symptoms of mercurialism, such as nephritis and ulcerative stomatitis, may also be present.

Silver.—Long-continued ingestion of this drug produces a peculiar slaty-grey pigmentation of the skin, generally universal, but most marked on the exposed parts. It scarcely comes under the heading of inflammations, but is included for the sake of convenience.

PROTEIN-CONTAINING DRUGS.—These include the antitoxin sera and bacterial vaccines. Vaccines rarely cause marked cutaneous eruptions, but when they occur they are of similar nature to those produced by sera. Serum eruptions form a very interesting group, as it is reasonable to suppose that their method of production is closely analogous to that of those toxic eruptions whose ætiology is obscure. For it has been assumed that these are due either to absorption of poisonous proteins produced by the body or to the toxins of pathogenic bacteria which are present in the body.

Serum eruptions are supposed to be an anaphylactic phenomenon and, though this seems to be a reasonable explanation in those cases where the rashes follow a second injection of a foreign protein given at least 14 days after the first, it does not fit in so well for cases in which the eruption follows the first injection of serum.

Symptoms.—Any of the above-mentioned non-specific eruptions may develop, but there is a greater tendency for the lesions to be of the *erythema*

multiforme type. Often the rash is very extensive, the trunk, face, and limbs being covered with disk-like, sharply circumscribed, infiltrated red lesions; these often become bullous, and hæmorrhages may occur in the centre of the lesions. In other cases ringed lesions occur, which spread peripherally and clear in the centre—*erythema gyratum*. Not infrequently these lesions are associated with fever, and pain and swelling in the joints, and gastro-intestinal disturbances, such as diarrhoea and vomiting, and albuminuria. In other cases the lesions are more of an urticarial nature, with transitory, very itchy wheals and swelling of the skin of the face. These eruptions usually come out about a week or 10 days after the injection of the serum, and clear up in about the same time.

Similar eruptions sometimes develop in persons vaccinated against small-pox, though in addition a true vaccinal eruption, in which the lesions have the characters of the vaccine vesicles, may develop.

Urticarial lesions develop in certain individuals who are sensitive to certain food-stuffs, after ingestion of these substances. They will be considered more fully under Urticaria (p. 1325).

Treatment.—Speaking generally, the first thing is to stop the drug causing the eruption. In the erythematous and urticarial types local soothing lotions are indicated, of which the most useful are lead and opium lotion; or liq. potass., \mathfrak{ss} ; sp. vin. rect., \mathfrak{ss} ; aq. ros. ad \mathfrak{ssviii} ; or ac. carbol., \mathfrak{ss} ; glycerin., \mathfrak{ss} ; aquam ad \mathfrak{ssviii} . Alkaline and bran baths are often very useful.

In the serum eruptions, calcium chloride or lactate is recommended and may be given in 10-grain doses three times a day. Quinine, grs. i or ij three or four times a day, is sometimes of value. In the more severe cases the patient must be kept in bed.

THE ERYTHEMATA

The term erythema may be used to signify any transient redness of the skin, such redness being frequently produced by external irritants; and these have already been dealt with under the superficial inflammatory dermatoses. When, however, the term is used to describe a composite clinical picture, two main types have to be considered, namely, the non-infiltrative and the infiltrative.

THE NON-INFILTRATIVE ERYTHEMATA

These include two classes, the congestive and the inflammatory. The congestive type has little or no dermatological importance. It is seen in blushing, which is a pure vasomotor phenomenon, and also in such transitory rashes as that seen during ether administration. The inflammatory type includes the rashes seen in scarlet fever, measles and röteln, drug eruptions just referred to, and certain other toxic conditions.

Ætiology.—One of the commonest varieties of erythematous rashes is that occurring as the result of septic absorption from a wound, and many of the cases of so-called surgical and puerperal scarlet fever belong to this group. They also occur in ptomaine poisoning and in other infections of the gastro-intestinal tract, but there always remain a number of cases in which no cause can be found.

Symptoms.—Erythematous rashes are usually of either the scarlatini-form, morbilliform or figurate type. The scarlatini-form cases differ from true scarlet fever in the absence of other typical signs, such as high temperature combined with rapid pulse, the date of appearance of the rash, the presence of sore throat and the characteristic appearance of the tongue. The morbilliform erythemata differ from measles in the absence of coryza, conjunctivitis and respiratory catarrh. The temperature is atypical and Koplik spots are not found. The figurate variety consists of patches or groups of disk-like lesions which tend to spread peripherally and clear in the centre so as to leave circinate and gyrate patterns. It is seen most commonly in drug eruptions, and can hardly be confused with anything else. In all these varieties as the eruption subsides there is a tendency to scaling, usually of the fine branny type, and this may often be extensive; the glove-like scaling of the palms and soles, seen in scarlet fever, may also occur in the simple types of erythema.

Hæmorrhage may sometimes take place into the erythematous patches, especially when these occur on the lower limbs. Most cases of simple purpura really belong to the erythema group. The mucous membranes may be affected similarly to the skin, and other general symptoms, such as diarrhœa, vomiting, fever and albuminuria, may be present.

Treatment.—Attempts must be made to find and remove the cause. All possible septic foci, such as pyorrhœa, tonsillar sepsis and chronic appendix trouble, should be dealt with. The bowels should be made to act freely and a light diet ordered. Cases should generally be put to bed, and always when there is fever or any marked constitutional symptoms.

THE INFILTRATIVE ERYTHEMATA. ERYTHEMA MULTIFORME

Ætiology.—Erythema multiforme may occur as a drug eruption, and especially as a serum eruption, as already noted, but it generally appears without any special cause being determinable. It occurs especially in young adults and may often recur, some cases doing so year after year at regular intervals. Individual attacks may clear up rapidly, but in many cases fresh crops appear, and the disease may go on for weeks or months. The joint swellings which sometimes accompany the skin lesions led to the supposition that the condition was of rheumatic origin, but it is probable that these are only a manifestation of a similar affection of the synovia of the joints.

Pathology.—Microscopic examination shows a dilatation of the vessels of the dermis with a leucocytic exudation. There is much local œdema. The epidermis is œdematous and fluid may accumulate beneath the horny layer or less frequently beneath the epidermis.

Symptoms.—The lesions of erythema multiforme differ from those mentioned in the last section in forming raised infiltrated lesions, which vary in size from a pea to a five-shilling piece or larger, and which have a well-defined distribution. They are usually found on the backs of the hands, wrists, and forearms and on the face, but are not infrequently found on the palms, and may also involve the trunk and lower limbs. In the milder cases they consist of red papules and patches with a sharply-defined border and are usually completely circular in outline. In the more severe forms hæmorrhages occur in the centre, or they become surmounted by bullæ. There

is some tendency to slow peripheral extension, with clearing up of the centre, so that ringed lesions may be formed. In these a play of colours may be noted, the outer red ring surrounding a purple hæmorrhagic ring, which in its turn surrounds a brownish pigmented centre; these lesions are sometimes called *erythema iris*. In rare cases the bullæ so predominate as closely to resemble a *pemphigus*. The subjective symptoms are often slight, but sometimes itching and burning occur. Lesions may appear on the mucous membranes. Pain and swelling in the joints are not infrequent, and gastro-intestinal disturbance may occur, as may also fever and albuminuria.

Treatment.—Care must first be taken to remove any possible cause. Of the drugs which are of value are calcium lactate, the salicylates and quinine. The former is best given in 5ss. doses on alternate nights. Local treatment is not really necessary, but calamine lotion or liniment may be applied to relieve itching or burning.

Erythema nodosum is closely related to erythema multiforme, and is dealt with on p. 301.

GRANULOMA ANNULARE

This is a very chronic, raised, ringed eruption, of dead white colour, seen chiefly on the dorsum of the hands.

Ætiology and Pathology.—The cause of this condition is unknown, but various intermediate types between it and erythema multiforme have been noticed, and this suggests a relationship with the latter condition. Histologically a dense cellular infiltration, associated with degeneration of the collagen bundles, is found in the deeper layers of the dermis, especially in the neighbourhood of the sweat coils.

Symptoms.—The earliest lesions are lentil-sized white nodules, seen most commonly on the back of the finger joints. Such lesions often occur in groups. They spread slowly, the centre of the group becoming flattened, and surrounded by a raised, dead white festooned margin, which can be seen to be made up of nodules of the same character as those of the original lesions. The disease is very slowly progressive, and may last for months or years if not treated. The lesions are generally localised to the hands and wrists, but are occasionally seen in other parts of the body, such as the nape of the neck, the buttocks, elbows and knees. In some cases subcutaneous fibrous nodules have been described in the neighbourhood of the elbow joints and elsewhere. Subjective symptoms are generally absent.

Treatment.—Internally, quinine and the salicylates may be given. X rays will often cause the lesions to disappear, but no other local treatment has much effect.

THE PURPURAS

The purpuras form a group which are closely related to the erythemata and are very often erythematous at the start. In them, however, the blood vessel walls are damaged and hæmorrhage occurs into the dermis. They may be of toxic or of bacterial origin. They are considered in detail on p. 725.

THE URTICARIAS

The urticarial eruptions are characterised by the presence of wheals, or localised areas of œdema. These are usually transitory in character and are accompanied by severe itching. Several different forms are recognised—

(1) Simple urticaria, (2) factitious urticaria, (3) giant urticaria, (4) papular urticaria, and (5) urticaria pigmentosa.

Ætiology.—As is pointed out above, urticaria can be produced by the ingestion of certain drugs and by injections of foreign sera. It can also be produced by the ingestion of certain food-stuffs in susceptible persons; for example, porridge, strawberries, shell-fish, eggs and milk. It also occurs after the consumption of decomposing food. As far as is known it is never due to the direct attack of any micro-organism. It is clear that it may be produced not only by protein poisons, but by non-protein poisons circulating in the blood. The actual mechanism by which the lesions are produced is not altogether clear. At one time it was thought to be a pure vasomotor neurosis, and that the poisons mentioned acted on the vasomotor centres; but in recent years it has been demonstrated that the lesions are true inflammations, and, therefore, it is probable that the action of the poison concerned is a local one. At the same time external stimuli, such as friction, seem, in many cases, to play a part in determining the points where the poison acts. It must also be noted that urticarial lesions may be directly produced by the injection of poisons into the skin. This is well seen in the bites and stings of insects, and the stings of plants, such as the nettle. In a large number of cases of urticaria, however, it is difficult to find any cause, and these are usually considered to be auto-toxic. The auto-toxin may be generated in the intestinal tract, or in infected foci, such as septic tonsils and teeth and inflammatory trouble in the pelvis. In the giant urticaria cases there is usually a considerable functional element present, and these cases are sometimes considered to be a vasomotor neurosis. Nothing is known of the ætiology of urticaria pigmentosa.

Symptoms.—*Simple urticaria.*—This is the form most frequently met with in adults. It may occur in an acute or in a chronic form. In the former the eruption appears suddenly, is often accompanied by general symptoms, such as fever, diarrhœa and vomiting, and subsides more or less rapidly. In the chronic type the eruption appears in crops; the individual lesions run a more or less rapid course, but fresh crops continue to come out at intervals and the condition may persist for many weeks, months or even years.

The lesions of simple urticaria are in their earliest stages pale pink papules or patches, varying in size from a pea to an inch or two in diameter. In a short time—sometimes a few minutes, at others an hour or so—the central part of the patch becomes a dead white colour, is firm to the touch and raised a millimetre or two from the surrounding skin. The lesions are intensely itchy. They may be few in number or very numerous; sometimes the whole body may be covered with patches of all shapes and sizes, and figurate patches are common. The eruption is most common on the trunk, but any part of the body, including the mucous membranes, may be affected.

Rarely hæmorrhages occur into the patches, and still more rarely do vesicles or bullæ surmount the patches.

Factitious urticaria.—This is a condition of the skin in which the slightest trauma, such as a slight scratch, will bring out a wheal. This condition is often present in simple urticaria, but frequently exists apart from any spontaneous eruption. The condition is sometimes referred to as *dermatographism*, as it is possible to produce letters in urticarial wheals on the patient.

Giant urticaria.—In this condition the lesions are not so much wheals as circumscribed patches of œdema. They are particularly liable to occur about the face—the eyelids, cheeks and lips often swelling up quite suddenly—burning or itching being an accompanying phenomenon. The mucous membranes are not infrequently attacked, and in a few cases sudden œdema of the larynx may produce dangerous asphyxial symptoms. The lesions are very prone to recur, and these recurrences may persist for years. This condition is sometimes spoken of as *angio-neurotic œdema* (see p. 978).

Papular urticaria.—This type is really only a variant of simple urticaria, but is that commonly seen in infants and young children. It is not very commonly seen in breast-fed infants, though it does occur, but otherwise is chiefly seen in the first two years of life; it may in some cases, however, persist, with intermission, up to about 7 years of age. The lesions appear, just like those of the adult form, as pink oval patches, usually about $\frac{1}{2}$ inch in diameter, but instead of the bulk of the whole patch being converted into a wheal only a central pinhead-sized wheal is produced. Itching is intense and often paroxysmal. When the lesion is scratched the central papule becomes inflamed and a bloodstained crust is formed on its summit, and it persists after the surrounding pink zone has disappeared. The cases usually present discrete pinhead-sized papules, covered with bloodstained crusts, suggesting a parasitic origin.

The eruption comes out in crops, especially at night, and chiefly on the lower part of the trunk and thighs, but may occur almost anywhere on the body. The children seem to suffer little in general health, though sleep at night is often lost, its effects being often more obvious in the parents.

Urticaria pigmentosa.—This is a rare condition and it is still a question whether it should be grouped with the other urticarias. It is chiefly a disease of infancy, but a certain number of adult cases are on record. The condition may appear within the first few days of life, and in a few cases lesions are said to have been present at birth.

The lesions usually appear as wheals, $\frac{1}{4}$ to $\frac{1}{2}$ inch in diameter; and as these disappear a yellowish-brown colour is left, and the lesion may remain raised above the surrounding skin or may flatten down to a pigmentary macule. These pigmented lesions may persist for many months or years. Itching may or may not be present. Sometimes marked factitious urticaria can be elicited. It would appear that occasionally simple urticarial lesions may leave behind pigmentation, but the condition described above is something quite distinct. In true urticaria pigmentosa there is generally a great increase in the mast-cells of the dermis which is absent in ordinary urticaria leaving pigmentation.

Diagnosis.—Simple urticaria may be confused with dermatitis herpetiformis and with the premycotic stage of mycosis fungoides. In the former, small deep-seated vesicles usually occur; but as they are not always present the diagnosis may be difficult. From the latter a diagnosis cannot be made with certainty, though when occurring in old people and persistent, mycosis fungoides must be considered.

The giant forms must be distinguished from erysipelas and acute erythematous eczema. In the former, high temperature is present, the lesion has a sharply defined, slowly spreading margin, and is often blistered. In the latter, the eruption is extensive and symmetrical, the skin is red, and vesicles

are frequently present. Chronic erysipelas of the lip is a persistent, slowly increasing condition and usually arises from a persistent crack in the lip, while urticaria has a sudden onset and disappears again.

Papular urticaria in children is most frequently confused with scabies. The diagnosis can be settled by the presence of burrows and the finding of acari in the latter condition.

Urticaria pigmentosa is not likely to be confused with any other condition.

Treatment.—If a cause can be found it must be removed: articles of diet known to cause the eruption must be avoided and all possible septic foci dealt with. If the cause is not clear, various types of food must be stopped one by one in order to exclude a possible source of trouble. Recently a cuti-reaction to various food-stuffs has been devised to detect the causative agent, and it is possible to desensitise patients from the particular poison to which they are susceptible. Apart from this, mild purgation and the administration of intestinal antiseptics, such as salol, ichthyol, creosote and calomel, can be recommended. Some patients improve on tonic drugs, such as iron, arsenic and quinine. Calcium chloride or lactate given over prolonged periods is efficacious in some cases. In others complete freedom from work and even rest in bed are necessary.

In the papular form in children excessive intake of sugar plays a part in a proportion of cases, and by a rigid cutting down of jams, sweets, etc., relief is often obtained.

In the giant form nerve sedatives, such as valerian and the bromides, are of value.

Locally, anti-pruritic lotions are most useful. Solution of coal tar and subacetate of lead, $\mathfrak{z}\text{ij}$ of each to $\mathfrak{z}\text{viij}$ of water; or liq. potassæ, $\mathfrak{z}\text{i}$, glycerine $\mathfrak{z}\text{i}$ to $\mathfrak{z}\text{viij}$ of water, may be used and can be applied frequently; alkaline and bran baths also give considerable relief. In children a teaspoonful of liq. picis carbon. added to a warm bath before going to bed is a valuable remedy, and in some cases sulphur ointment grs. xv to $\mathfrak{z}\text{i}$ has proved useful but lotions are usually better tolerated.

There is no known treatment which affects urticaria pigmentosa.

PRURIGO

Prurigo of Hebra is a condition which is rare in this country, but is not uncommon in Eastern Europe. It is apparently closely connected with the urticarias, but some authors consider it a distinct affection. It begins usually in the first or second year of life, by the appearance of intensely itchy, pin-head- to lentil-sized papules on the extensor aspects of the limbs, chiefly on the legs and forearms; these soon become covered with blood-stained crusts, and eventually the whole of the skin of the affected area becomes thickened (lichenified), pigmented and excoriated. The lesions may eventually involve the whole of the limbs, but the flexures usually escape. The trunk, neck and face may become eczematised and lichenified. The glands in the groins and axillæ become much enlarged. The milder cases (prurigo mitis) may eventually respond to treatment and get well about the time of puberty, but the more severe cases (prurigo ferox) persist throughout life. The patient eventually succumbing to the disease.

Treatment.—There is no specific treatment. Baths and sedative lotions

and ointments, together with sedative drugs, to relieve itching and to ensure sleep, should be employed.

DERMATITIS HERPETIFORMIS

Dermatitis herpetiformis or Duhring's disease is a condition characterised by the appearance on the body of crops of erythematous or urticarial papules or patches, usually surmounted by herpetic vesicles or bullæ, and giving rise to intense itching.

The evidence for placing this disease among the toxic eruptions is not conclusive, but is sufficiently suggestive to make it justifiable. In this connection may be mentioned its occurrence as one of the rarer toxæmias of pregnancy (hydra gestationis), and its close clinical resemblance, in some cases, to the urticarias and the erythemata.

Ætiology and Pathology.—The disease may occur at any time of life; it is rare in infancy and childhood, although cases have been reported; it is fairly common in young adult life, but most cases occur in middle life. Both sexes are pretty equally attacked. A special form occurs in association with pregnancy, and is apt to recur with each pregnancy. The malady does not appear to be associated with the presence of any particular micro-organism in the body, and cultures from vesicles and bullæ are sterile in their early stages. Blood cultures are also negative.

It has been considered by some to be due to some nervous derangement, and it is true that it is sometimes associated with neuroses; it is probable, however, that these are a product rather than a cause of the disease. It is probable that the condition is produced by an unknown toxin.

Microscopically lesions show a dense, cellular infiltration of the superficial part of the dermis, chiefly around the vessels. There is always considerable superficial œdema, which in the vesicular and bullous cases collects under the epidermis, lifting it from the underlying dermis; the fluid and the vesicles contain a large number of eosinophil corpuscles.

Symptoms.—The eruption is essentially polymorphous, that is to say, all the types of lesions mentioned above may be present in the same case at the same time. Most commonly the lesions look like irregularly figurate urticarial wheals which are surmounted by numerous shotty vesicles. In other cases the lesions are more frankly erythematous, while in others larger vesicles or bullæ form, either with or without an underlying erythematous or urticarial patch. In all cases, except when the bullæ are large, there is intense itching in the lesions, with the result that they are scratched, and small bloodstained crusts or excoriations are seen mixed up with the other manifestations of the disease. The limbs and the trunk are most frequently affected, but any part of the cutaneous surface may be involved, though rarely the palms and soles, and the mucosæ are attacked in a considerable percentage of cases. There is a great tendency for the lesions to recur, fresh crops coming out at frequent intervals, and the disease may persist for years; the writer has under his care a case of over 40 years' duration.

The general health usually suffers very little, in spite of the fact that sleep is often disturbed. Gastro-intestinal symptoms, such as diarrhœa and vomiting, may occasionally occur, and in fatal cases lesions have been

found in the gastro-intestinal tract, which possibly account for the above-mentioned symptoms. An increase in the eosinophil corpuscles in the blood occurs in the majority of cases.

Diagnosis.—From erythema multiforme it can be distinguished by the irregular distribution, the shape and the polymorphic character of the lesions in conjunction with the intense itching which occurs; from urticaria by the presence of vesicles and bullæ, which are almost unknown in simple urticaria, though not infrequent in the papular variety, and by the persistence and recurrence of the lesions; and from pemphigus by the itching, the polymorphous character of the lesions, and the comparatively slight effect on the general health.

Treatment.—This calls for much patience on the part both of the patient and the physician. In the first place a careful examination, both clinical and bacteriological, must be made to find any focus of disease. Of the internal remedies most reliance has been placed on arsenic, and in some cases the eruption ceases when a certain dose is reached; but this is by no means always the case. Arsenic may be given by the mouth as Fowler's solution or Asiatic pill, or by injection, the cacodylate of soda, enesol and salvarsan being the favourite preparations. The dose should be small to start with, and increased to the limit of tolerance; and the drug should be discontinued if no definite result is obtained. Aperients and saline lavage of the bowel are satisfactory in severe cases; in others quinine, salicin and sodium bicarbonate have proved successful. In any case attempts should be made to check the itching. Alcohol and coffee should be stopped, and also all excess of sugar in the diet. Phenacetin and antipyrine are useful, and trional may be given occasionally at night. The injection of certain non-specific protein substances, such as the patient's own blood, horse serum, sterilised milk or peptone, has occasionally produced a cure.

Local remedies consist mainly of anti-pruritic applications. The most useful is a lotion containing 2 to 3 per cent. carbolic acid, 1 per cent. liq. potassæ, or 2 to 5 per cent. liq. picis carbonis. Alkaline and bran baths are valuable, especially in the bullous cases—in which cases also weak (5 per cent.) sulphur ointment sometimes acts well.

PEMPHIGUS

An inflammatory condition of the skin, characterised by the eruption of blisters usually occurring in crops, and associated with constitutional symptoms.

Four different varieties are recognised: (1) acute pemphigus, (2) chronic (pemphigus vulgaris), (3) pemphigus foliaceus, and (4) pemphigus vegetans. Acute pemphigus is now known to be a definite bacterial infection, and should not strictly be included in this group; but it is placed here for convenience of description. In the other three varieties the cause is unknown, but it is believed that they are of toxic origin.

ACUTE PEMPHIGUS

Ætiology.—This is a rare condition which occurs almost entirely in butchers, and appears to be due to inoculation of some abrasion with a

pathogenic micro-organism, the diplococcus of Pernet and Bulloch. The lesions are not produced by local spread, as in impetigo contagiosa, but are distributed through the blood stream, and symptoms of acute toxæmia occur simultaneously with (or even before) the appearance of the eruption. The diplococcus can be obtained from the bullæ, as well as from the blood.

Symptoms.—The disease commences acutely with fever, malaise, nausea and vomiting. Bullæ then appear suddenly on the apparently normal skin; they are usually very numerous, and as big as a pigeon's or hen's egg. They may burst, leaving a red oozing surface. The lesions usually involve the mucous membranes of the mouth and throat, and even of the intestinal tract, causing pain and difficulty in swallowing, diarrhœa and vomiting, and secondary bronchitic and broncho-pneumonic complications. In a large proportion of cases a general septicæmic condition supervenes and the patient dies, but in a few milder cases the lesions dry up and the patient recovers. Rarely cases may become chronic.

Treatment.—The cases are so infrequently seen that little can be said on this point. The main principles are to keep the patient in bed, puncture the vesicles, and apply mild antiseptic dressing, e.g. 1 in 4000 perchloride of mercury, with a thin layer of paraffin gauze between it and the skin, or some such dressing which will not cause poisonous symptoms by absorption. Quinine is recommended as the best internal remedy. No observations have been made, as far as the writer knows, with regard to specific therapy.

CHRONIC PEMPHIGUS

Symptoms.—The affection, which is also rare, is characterised by the appearance of crops of bullæ in various parts of the skin and mucous membranes, each bulla appearing on the skin without any pre-existing erythematous or urticarial lesion. The eruption is not associated with itching, but the general health suffers, thus differing from dermatitis herpetiformis. Further, the bullæ are usually sterile in their early stages, though both the *Staphylococcus pyogenes albus* and the *Bacillus pyocyaneus* have been found; but these are almost certainly secondary infections.

The bullæ usually dry up in the course of a week, leaving an erythematous and scaly patch, which subsequently disappears; but fresh crops of blisters constantly come out, and this state of affairs may persist for months and years. The general tendency is for the disease to continue, while the general health steadily deteriorates, and finally death supervenes.

Diagnosis.—This has to be made from dermatitis herpetiformis and from the bullous form of erythema multiforme. The main points in the diagnosis of the former have been considered in a preceding paragraph. In erythema multiforme the lesions are especially distributed on the extremities, and some of them show the definite coin-shaped erythematous patches. The attack usually lasts only a week or two.

Treatment.—This is very unsatisfactory. Arsenic in full doses has given good results, and quinine and salicin are also recommended. Gastro-intestinal antiseptics and colon lavage are useful. Intramuscular injection of horse serum, or of the patient's own serum, may be tried. Local treatment is the same as for acute pemphigus.

PEMPHIGUS FOLIACEUS

This is probably only an extensive type of chronic pemphigus.

Symptoms.—Bullæ appear frequently and over large areas of the body, and as a result set up a condition resembling generalised exfoliative dermatitis. When this stage is reached fresh bullæ are not properly formed, owing to the permeability of the improperly formed horny layer, abortive flaccid lesions constantly appearing on the affected areas. Crusting, scaling and a tendency to warty formations, together with much pigmentation, is present. The trunk, neck, face, scalp and limbs may all be attacked, but usually the hands and feet are much less affected.

The general health is usually much affected; but this is not always so. The writer has at present under his observation a case of 20 years' duration which, apart from the skin condition, is otherwise well. Usually, however, cases end fatally in a year or two.

Diagnosis.—The only condition likely to be confused with this is generalised exfoliative dermatitis; but in this latter condition bullous formation is absent.

Treatment.—This is the same as for chronic pemphigus.

PEMPHIGUS VEGETANS

Symptoms.—The lesions in this type frequently first appear in the mucous membrane of the mouth, but may appear on other parts of the body. When fully developed they are chiefly localised to the flexures of the axillæ, elbows, groins, knees and around the anus and vulva. The initial lesion is a flaccid blister, which on rupture develops fungating granulations from its base, which discharge much fetid secretion. The patient's health suffers rapidly from septic absorption, and he usually succumbs in the course of a few months.

Diagnosis.—The condition when fully established is characteristic, but in the early stages the lesions might be mistaken for syphilitic mucous tubercles. The diagnosis can be settled by the presence of other syphilitic lesions, by finding the spirochæta pallida, and by the Wassermann reaction.

Treatment.—No treatment is known to influence the course of the disease. Local antiseptics are required for the lesions, weak perchloride of mercury and eusol being the most likely to be satisfactory. Otherwise treatment is on the same lines as for pemphigus chronicus.

DERMATITIS EXFOLIATIVA

This is a generalised inflammation of the skin, characterised by redness and profuse scaling. There are many types of this condition, and divers causes. It is customary to divide dermatitis exfoliativa into primary and secondary varieties. The former occurs without any pre-existing dermatosis, while the latter really represents the generalisation of some other skin inflammation, such as eczema, seborrhœic dermatitis or psoriasis. When such diseases generalise there is a tendency for them to take on the character of a primary exfoliative dermatitis, presently to be described.

The primary variety occurs in its most striking form in salvarsan poison-

ing, and may also occur in such diseases as leukæmia and mycosis fungoides—diseases closely related to one another. There still remain, however, a number of cases in which no cause can be found, and which we are probably justified in considering as toxic eruptions.

Symptoms.—The cases due to salvarsan may be taken as typical of the group. In these the eruption usually commences as bright, scarlatiniform patches on the flexor aspect of the forearms and on the abdomen and chest. The rash spreads rapidly, so that in a day or two the whole body is covered. At first it is found to consist of distinct pinhead-sized macules, chiefly around the follicles, but soon it becomes one continuous red sheet. Almost immediately the eruption begins to scale; the scales may be of the fine branny type, or large like fish scales. The amount varies in different cases, but is often very considerable, the bed having to be swept out several times a day. The onset is not always as described; sometimes the initial eruption is an urticaria, or even like an acute erythematous eczema, involving the face and forearms, and in a case recently under the writer's care it was erythemato-vesicular at the commencement. Once the eruption is fully established it usually takes 2 to 3 months to disappear. In an uncomplicated case the rash gradually subsides, scaling ceases, and the skin assumes its normal colour, though some thickening may remain for a considerable time. The flexures of the limb and the neck usually are the last to clear. The hair is frequently completely shed, but grows again later, and the nails may also be lost temporarily, though this is less frequent. An irregular thickening of the nails is, however, more common. At the onset there may be fever, malaise and intestinal disturbance; later, in the course of 3 to 4 weeks, bronchitis and broncho-pneumonia may supervene, and sometimes cause a fatal issue. Nephritis may also occur, and may cause permanent renal changes. If careful nursing is not provided the skin may become infected, and septic absorption may occur. There is always much enlargement of the lymphatic glands, which are soft and spongy, and conjunctivitis is sometimes present.

Most of the idiopathic cases run a similar course; but several different varieties have been described, among which the condition known as pityriasis rubra of Hebra is apt to be associated with visceral complications and with skin atrophy, and runs a very fatal course.

Diagnosis.—The primary cases must be distinguished from those due to leukæmia and mycosis fungoides. In the former the blood picture will probably clear the diagnosis, and in the latter the severe itching, which usually accompanies it, and which is usually absent in the simple exfoliative dermatitis cases.

Prognosis.—This is always uncertain and should be very guarded. Cases may clear up in 2 or 3 weeks, or may persist for years, with gradually increasing prostration ending in death.

Treatment.—In the salvarsan cases sulphur appears to be the best remedy. It may be given as sodium thiosulphate by intravenous injection, or as intramine or contramine, as recommended by McDonagh. The main internal remedies must be directed to maintaining the general health, and to countering complications as they arise. Complete rest in bed is indicated in all cases, however mild they may at first appear, and the warmth of the body must be maintained. Warm bran baths may be given if no fever is

present, and dusting the skin with talc powder makes the patient comfortable. Local septic complications must be dealt with by mild antiseptic creams or pastes.

ERUPTIONS DUE TO BACTERIA AND FUNGI

Having dealt with the deep inflammatory dermatoses produced by toxins circulating in the blood, it is now necessary to consider those which are caused by living organisms reaching the skin by the same channels. Three of these form a very important group of dermatoses, namely, tuberculosis, syphilis and leprosy. The two latter have been dealt with on pp. 190 and 117 respectively. There are, however, certain others which require notice. It is probable that the eruptions of certain specific fevers may be due to the presence of the infecting organisms in the tissues; this is known to be the case in the rose spots of typhoid fever, and is probably the case in variola and varicella. The erythematous and purpuric eruptions sometimes seen in malignant endocarditis and other septicæmic and pyæmic conditions are also probably due to the direct action of the streptococcus, while it will be necessary later to describe the cutaneous manifestations produced by the gonococcus when it enters the blood stream.

TUBERCULOSIS CUTIS

The tubercle bacillus may attack the skin in several different ways. The commonest variety is a superficial granulomatous formation known as lupus vulgaris; this variety can apparently be produced both by local inoculation and through the blood stream. Lupus verrucosus, a variant of this type, is always a local inoculation, and is accompanied by warty overgrowths. Miliary tuberculosis of the skin may accompany general miliary tuberculosis, and local tuberculous ulcers may also form, but are chiefly seen on the mucous membranes. In addition, an infection of the skin may occur when a tuberculous abscess, either from a suppurating lymphatic gland or bone, bursts through the skin, and this is spoken of as scrofuloderma. There are also groups of cutaneous and subcutaneous tuberculous lesions, produced by bacilli circulating in the blood, which are called tuberculides, and include several varieties, the lichenoid or lichen scrofulosorum, the acneiform or acne scrofulosorum, the papulo-necrotic, and the gummatous (erythema induratum or Bazin's disease).

LUPUS VULGARIS

Pathology.—The lupus nodule is composed of a group of ordinary miliary tubercles, such as are seen in the lungs and elsewhere. It consists of groups of epithelioid cells, surrounding giant cells, often with peripherally arranged nuclei, the whole being surrounded by a dense mass of round cells. Tubercle bacilli have been demonstrated in the lesions, and inoculation into guinea-pigs will produce tuberculous lesions.

Symptoms.—Lupus vulgaris usually attacks the face; but it is not uncommon to find patches on other parts of the body. In this latter site it may be symmetrical. Usually on the face it is asymmetrical. It is most

frequent on the nose or cheek, and frequently begins in childhood. The earliest lesion is a small, dull red pinhead-sized spot, to which other similar spots are soon added, the whole being surrounded by an erythematous zone. On pressure with a lens, however, these original spots can be distinctly seen as yellowish points or nodules compared in appearance to apple jelly. They are very soft, and if a pointed match is applied to one of them it sinks easily into the nodule. These patches may slowly spread so as to involve considerable areas, and may persist for a long period without ulceration. In other cases, however, ulceration may supervene, and considerable destruction of tissue take place, especially on the nose, which is often completely destroyed up to the edges of the nasal bones. The bone itself is not attacked; but the cartilage may completely disappear. If healing occurs, a soft, superficial scar is produced; but fresh nodules are liable to appear in it. Any part of the face may be attacked; but the scalp usually escapes. The glands in the neck may enlarge and occasionally break down, but this is uncommon. Facial lupus vulgaris is frequently complicated by similar lesions in the mucosa of the nose and mouth, and these situations are sometimes the primary seat of the disease. On the mucous membranes the nodules are not visible, but sharply defined, raised, rather warty-looking patches occur. It is commonly seen on the inner aspects of the cheek, gums, palate and nasal mucosa; but the pharynx and larynx may be involved.

On the body the patches may attain great dimensions; they often spread at the margins and heal in the centre, forming irregular gyrate patterns. As a rule they are of the non-ulcerating type; but in some cases ulceration occurs. In some cases, too, considerable contraction of the skin results, leading to deformity; in others the lymphatic vessels become blocked, and a condition of elephantiasis may supervene.

The disease usually spreads very slowly, and lasts a great number of years. Some cases remain practically stationary almost indefinitely. A few, however, spread rapidly and defy treatment.

In old-standing cases there is a definite tendency to the development of carcinoma. This is of the squamous type, and does not as a rule give rise to secondary carcinomatous glands. It can, therefore, generally be removed locally.

Diagnosis.—Lupus vulgaris is most easily confused with lupus erythematosus (p. 1349). In the former definite nodules are present, and there is a tendency to ulceration; the disease usually begins in childhood and persists for many years. In the latter the disease is non-ulcerative, has a great tendency to be symmetrical, rarely appears before adult life, and is especially liable to occur in the middle-aged. The scalp is often attacked, while this is rare in lupus vulgaris. In lupus erythematosus thick adherent scales, fixed down by epithelial plugs, form, and the scar is often covered with pits of varying size; in lupus vulgaris the scale is of a very superficial type and easily removed, and there are no plugs.

From tertiary syphilis the diagnosis may occasionally be difficult, and the two conditions may be combined. The absence of nodules, the tendency to form sharply cut, rather deep ulcers, the presence of a positive Wassermann reaction, and the rapid response to anti-syphilitic remedies will generally settle the diagnosis.

Rodent ulcer is distinguished by its appearance fairly late in life, by its

firm rolled edges of pearly white colour, and by its tendency to involve the bony structures of the face.

Treatment.—Of prime importance is the general health of the patient. Good ventilation, sunlight, warm clothing and plenty of good food are necessary if cases are to do well. In the absence of a good supply of natural sunlight, excellent results are obtained by exposing the body to the rays of the carbon-arc or mercury-vapour lamps. As to drugs, cod-liver oil, malt, iron and arsenic are often of considerable value.

Local measures should also be taken to destroy the lesions. Small patches may be excised; but this method is only rarely applicable. If the patches are non-ulcerating, and not too extensive, excellent results are obtained by the Finsen light; but this method is rarely available, and is very slow. The nodules may be destroyed by the application of 20 per cent. ac. salicylic plaster with creosote, or 10 per cent. pyrogallie acid ointment rubbed in daily until a violent reaction is produced. Recently Adamson has recommended rubbing acid nitrate of mercury into the patches, and this gives very satisfactory results. In the larger ulcerating patches a preliminary scraping, followed by the application of ac. nitrate of mercury or zinc chloride stick, is usually satisfactory. The use of X-rays and CO₂ snow has nothing to recommend it, and the former is very dangerous if given over prolonged periods.

LUPUS VERRUCOSUS

This is due to the local inoculation of the tubercle bacillus, and is chiefly seen in those who handle infected meat, and in those who conduct autopsies. It is also known as *verruca necrogenica* or *post-mortem wart*.

Symptoms.—The lesions usually occur on the hands, chiefly the dorsum and on the knuckles. The earliest lesion is a small, red, firm papule, which spreads slowly. The centre soon becomes raised and warty; but there is always a well-marked inflammatory zone around this warty growth. Serum and pus may exude between the papillæ of the wart, and the whole may be crusted. The lesion is generally single, and may attain several inches in diameter. Rarely numerous lesions are present.

Treatment.—Small lesions are best excised. Destruction by the actual cautery, or by diathermy, may be practised in some cases. In this variety a pastille dose of X-rays may flatten down the warty growth, and this may be followed by the use of salicylic acid or mercurial plasters, or by painting with acid nitrate of mercury.

LOCAL TUBERCULOUS ULCERS

These occur usually as complications of tuberculosis of other organs. They are frequently present on the mucous membranes, or around the orifices of the body. Little can be done except palliative treatment if they are numerous; but isolated ones can be destroyed by one of the methods already described.

SCROFULODERMIA

This term is applied to secondary infection of the skin from the bursting of deep-seated tuberculous abscesses. The lesions either take the form of a

thick crust overlying an area of unhealthy-looking granulation tissue, or are purplish-red shiny areas surrounding a sinus.

The term is also applied to single or multiple subcutaneous abscesses, not infrequently seen in children, which contain pus, in which numerous tubercle bacilli can be found. They are sometimes called *tuberculous gummata*.

Treatment.—The treatment of the underlying condition is essentially surgical and where possible the affected skin should be excised, otherwise scraping, followed by painting with acid nitrate of mercury, is the best treatment.

THE TUBERCULIDES

These lesions, which are due to the lodgment of tubercle bacilli in the peripheral capillaries, with the production of a local inflammatory reaction, differ from the foregoing tuberculous diseases of the skin in that there is no tendency for the individual lesions to spread. They are thus comparable to the secondary syphilides, and like them are of several different types.

THE LICHENOID TUBERCULIDE.—**Symptoms.**—This condition, also known as *lichen scrofulosorum*, is chiefly seen in young children with glandular tuberculosis. The lesions come out in crops, chiefly on the trunk, and are arranged in circular or oval groups, made up of pinhead-sized acuminate follicular papules. These lesions may be of the same colour as the normal skin, or of bright red colour. There is usually a small crust on the summit of each papule, or sometimes a small pustule. The disease lasts from a week or two to many months.

Diagnosis.—In lichen spinulosus there is less obvious inflammation, and a horny spine projects from the centre of the papule, which can be removed by forceps.

The small follicular syphilide occurs in adults, and is associated with other syphilitic phenomena.

Treatment.—No special treatment of the skin has any effect. The treatment is that for glandular tuberculosis.

THE ACNEIFORM TUBERCULIDE.—**Symptoms.**—This condition, also known as *acne scrofulosorum*, occurs in children and adolescents who are suffering from some form of tuberculosis, and chiefly affects the buttocks and thighs, but may be more extensive. The lesions are lentil-sized, acuminate, follicular papules and pustules, and are generally distributed discretely. They are of bright red colour and pustular or crusted.

Diagnosis.—The affection is sometimes difficult to diagnose from staphylococcal folliculitis; but the individual lesions run a much slower course, and are usually more numerous and not painful.

Treatment.—This is the same as for the lichenoid tuberculide.

THE PAPULO-NECROTIC TUBERCULIDE.—**Symptoms.**—In this variety of tuberculide the lesions are small lentil- to pea-sized nodules starting deep in the dermis or in the hypoderm, eventually softening and bursting through the skin with the production of a small, rather indolent ulcer. After healing, pitted scars are left. The lesions are usually numerous and come out in crops, which may continue to appear over a period of some years. The parts affected are chiefly the distal extremities of the limbs, e.g. the backs of the hands and feet, the sides of the fingers, and the extensor aspects of

the forearms and legs. Lesions in these regions have been named *follicles*. Somewhat similar lesions have been described on the face and termed *acnitis*, but it is still not quite clear that they belong to the same group; it is more probable that they are the same as the benign miliary sarcoid of Boeck (see p. 1339). The eruption nearly always occurs in patients who have some other manifestations of tuberculosis, and occurs chiefly in young adults.

Diagnosis.—These cases can be distinguished from *erythema multiforme* by their deeper site of origin, and by their tendency to ulcerate and produce soars.

Treatment.—As for other tuberculides. No local treatment has any effect on the lesions.

THE GUMMATOUS TUBERCULIDE.—**Symptoms.**—This condition, which also goes by the name of *erythema induratum* or *Bazin's disease*, is not uncommon, and is almost entirely confined to the legs, especially the calves, and is usually bilateral. It occurs chiefly in girls and young women between the ages of 15 and 25. The initial lesion is a deep-seated nodule, from a pea to a hazel-nut in size, starting in the subcutaneous fat. The nodule slowly increases in size, involves the skin, which becomes purplish in colour, and eventually softens and bursts. The ulcer thus produced has a ragged edge and an unhealthy purplish-red base, often covered by a dirty greenish slough. These ulcers are very sluggish, and take weeks or months to heal. Fresh lesions are constantly forming, and a dozen or more lesions may be found simultaneously on the two limbs. There is often considerable pain in the lesions.

Diagnosis.—From syphilitic *gummata*.—In this condition the lesions are less numerous—indeed often single—and are rarely so symmetrical. The lesions are usually painless. The edge of the ulcer is sharper and more cleanly cut, and the base is cleaner, or has a characteristic wash-leather slough. Other stigmata of syphilis may be present, and the Wassermann reaction is positive.

From the hypodermic sarcoids of Darier-Roussy.—In this condition somewhat similar nodules appear, but are usually fewer in number. They never break down or ulcerate, and occur at a later period of life, namely, in middle-aged women. The tuberculin reaction is usually negative.

Treatment.—The ulcers heal readily if the patient is kept in bed, but are liable to recur when she gets up again. General tonic treatment should be given, and in many cases salvarsan has proved to be a potent remedy. Locally antiseptic baths and dressings are required.

LUPUS PERNIO

This is a rare condition in which the nose, cheeks, ears and fingers become swollen and purplish in colour. At one time thought to be related either to lupus vulgaris or lupus erythematosus, it is now recognised as a distinct disease. It has been shown by Schaumann that the skin lesions are frequently associated with areas of rarefaction in the small bones of the hands and feet, and even of the larger bones. Granulomatous deposits also occur in the lymphatic glands and other lymphoid structures. It is closely related to the cutaneous sarcoids of Boeck described below.

THE SARCOIDS

Under this heading have been classified a heterogeneous group of *lomata*, which have a histological picture similar with that of the *cutaneous granulomata*, but have two features which differentiate them from tuberculosis, i.e.—(1) the lesions never break down and ulcerate, and (2) the results to tuberculin tests and inoculation experiments are negative for tuberculosis. Recently, however, Schaumann has claimed that he has cultured the bovine tubercle bacillus from lesions of cutaneous sarcoid and lupus pernio.

Two main types are recognised: the cutaneous of Boeck and the hypodermic sarcoid of Darier.

THE CUTANEOUS SARCOID OF BOECK

The *cutaneous sarcoid of Boeck* generally attacks the face and upper part of the body, and may appear in small nodules or in plaques. The small nodular variety is usually symmetrical, and the nodules are numerous; they are usually lentil- or pea-sized, firm to the touch, of deep reddish-brown colour, and tend to be arranged in groups, especially about the lower lids and chin. There is no tendency for them to break down, and they often persist for many months.

The other variety is usually asymmetrical, and the lesions often single or few in number. They occur chiefly about the ears, nose and cheeks. They form either large nodules or irregular infiltrated plaques of a purplish-red colour, and up to 1 to 2 inches in diameter. Both these varieties generally occur in middle-aged adults.

Diagnosis.—The condition has to be distinguished from lupus vulgaris, as brownish nodules are sometimes present. These, however, are much firmer than those of lupus vulgaris, and the pointed match does not sink into them.

Treatment.—Some cases clear up slowly under arsenic, especially salvarsan, and tuberculin is said to be beneficial in some cases; cod-liver oil is also beneficial. The writer has had good results from the intravenous injection of 3 per cent. sodium morrhuate solution, in doses of 1 to 2 c.c. once or twice weekly. General arc-light baths are also of considerable value.

THE HYPODERMIC SARCOID

The *hypodermic sarcoid* chiefly occurs about the lower limbs, but may also be seen on the trunk. It commences as deep, rather painful nodules in the subcutaneous fat, which may eventually involve the skin, producing a localised redness. The lesions do not break down; but some fibrous contraction may be present when the lesions subside. They are not usually very numerous.

Diagnosis.—This is from the nodular syphilides and from the tubercles. From the former they are separated by the absence of a positive Wassermann reaction, and by their chronicity; from the latter by their failure to ulcerate, and by the absence of positive inoculation experiments.

Treatment.—Darier recommends combined treatment with tuberculin and neosalvarsan.

GONORRHOEAL KERATOSIS

The lesions in this condition are probably produced by gonococci circulating in the blood stream, although they have not been demonstrated.

They occur in patients suffering from gonorrhoeal arthritis and other manifestations of general gonococcal infection, and usually appear on the palms and soles, though other parts of the hands and limbs may be affected.

The lesions are red patches covered with cone-shaped horny thickenings, and are generally numerous. In addition, a general hyperkeratosis of the palms and soles may occur.

Treatment.—General treatment for gonorrhoea is required, together with ung. ac. salicylic. locally.

SPOROTRICHOSIS

In addition to those bacterial conditions which attack the skin by way of the blood stream, a certain number do so by way of the lymphatics. Lymphangitis with abscess formation from pyogenic organisms is well known, and the same condition in tuberculosis has already been described under the title of "scrofuloderma." Actinomycosis is another such condition, and has already been dealt with (p. 177). Somewhat similar conditions to the two last mentioned may be produced by certain fungi, of which the only one which requires special notice is sporotrichosis.

Symptoms.—Infection may take place through a crack in the skin, usually on the hand or foot. From this a lymphangitis starts, which spreads up the affected limb, and subcutaneous cold abscesses soon appear at points along the affected lymphatics. These eventually burst and leave indolent fungating ulcers, which show little or no tendency to heal spontaneously. A good deal of pus or yellowish fluid exudes.

Diagnosis.—Cases are usually diagnosed as *tuberculosis*, and a certain diagnosis can only be made by obtaining the fungus in culture. This should be done on Sabouraud's proof medium and incubated at room temperature.

Treatment.—The lesions usually disappear under large doses of potassium iodide administered internally.

XANTHOMA

Xanthoma forms an interesting link between the inflammations due to chemical toxins circulating in the blood and those due to bacteria, for in this condition lesions of a granulomatous nature are produced around a deposit of a chemical substance in the tissues. Apart from this condition, all the granulomata whose nature is known are produced directly by bacteria; tubercle, syphilis and lepra are the best known examples.

Three clinical varieties of xanthoma are recognised: (1) *xanthoma tuberosum*, (2) *xanthoma diabeticorum*, and (3) *xanthoma planum*. This last variety has no connection with the first two, but is considered here for convenience.

Ætiology.—*Xanthoma tuberosum* and *diabeticorum* occur in patients who for some reason or other have an excess of cholesterin in the blood

serum. This is why one form is seen in diabetics. The cholesterol becomes deposited in the tissues and causes a reaction, chiefly among the fixed connective-tissue cells of the dermis, particularly the endothelial cells, and a granuloma not unlike that seen in tuberculosis is produced. Histologically the tumours of xanthoma consist of large cells, arranged around the vessels, containing droplets of a cholesterolin-fatty-acid-ester and some fat. Around these cells a varying degree of connective-tissue hypertrophy may occur.

Symptoms.—*Xanthoma tuberosum*.—In this condition numerous discrete yellowish nodules appear in the skin. These increase in size and may form tumours as big as an orange. They are most commonly seen on the extensor aspects of the limbs, especially on the elbows and knees, where they may form large firm tumours, but they may be seen on any part of the skin. The bones, tendons, viscera and mucous membranes may also be involved. The colour varies from a bright yellow to an orange or red. The disease is usually seen in young adults. It does not generally affect the general health, but is occasionally associated with jaundice. The lesions are very persistent.

Xanthoma diabeticorum.—The lesions are usually smaller and more numerous; they are lentil-sized lesions and come out in crops, usually on the buttocks and extensor surfaces of the limbs. They disappear rapidly under appropriate treatment for diabetes.

Treatment.—In the diabetic cases, the underlying disease must be treated. For xanthoma tuberosum no definite treatment can be laid down, but a diet which contains as little cholesterolin as possible should be prescribed.

Xanthoma planum.—**Ætiology.**—This has been considered to be a fatty degeneration of the fibres of the orbicularis palpebrarum muscle, but in some cases an excess of cholesterolin in the blood has been demonstrated.

Symptoms.—The lesions consist of flat, yellow, slightly raised patches, which are often symmetrically placed, on the eyelids near the inner canthus. They may be as small as a pin's head or may involve almost the whole eyelid. They produce no symptoms. They mostly occur in old people.

Treatment.—They can be destroyed by electrolysis or by caustics, or removed by excision.

C. INFLAMMATORY DERMATOSES OF NERVOUS ORIGIN

Apart from trophic conditions of the skin due to disturbances of the nervous system, and to which reference has already been made, there is only one condition which is known definitely to be associated with lesions of the nervous system, and that is herpes zoster.

HERPES ZOSTER

Ætiology and Pathology.—This condition is associated with inflammatory lesions of the posterior root ganglia. Some cases are the results of known poisons acting on these structures, as, for example, arsenic and the syphilitic virus. In the bulk of cases, however, no definite toxin can be found, and it is assumed that some unknown organism is the causative

agent. Recently much attention has been attracted to the supposed relationship of herpes zoster to varicella, but no common ætiological factor has yet been demonstrated.

Symptoms.—The attack is usually preceded by pain along one or more nerve trunks, generally one of the intercostal nerves, but the fifth cranial and any spinal nerve may be affected. In the course of a day or two crops of vesicles appear on an inflamed base. These vesicles are shotty and have little tendency to rupture. These crops are distributed along the course of the affected nerve. In the course of a week or so they dry up, often leaving a black gangrenous spot, which leads to pitted scarring.

Herpes zoster of the ophthalmic division of the fifth cranial nerve may cause damage to and even loss of the eye, and in any case usually causes much scarring. The glands in the neighbourhood are often enlarged. Recurrences are very rare, and it is thought that one attack immunises against another.

The neuralgic pain associated with zoster is often severe, especially in old people, though children are usually free from it. In an ordinary case it may precede the appearance of the eruption by several days, but it usually disappears when the eruption begins to subside. Occasionally, however, it persists for a considerable time after the eruption has subsided and may be of very severe character, entirely destroying sleep. It is often accompanied by acute hyperæsthesia of the skin.

Diagnosis.—This is easy, on account of the distribution along certain nerves and of the nerve pain.

Treatment.—As far as the local lesions are concerned, it is best to avoid moist applications; and, with the object of diminishing suppuration and subsequent scarring, they may be dressed with a bland talc and zinc oxide powder, or painted with collodion.

If, as is usual, there is pain, in the milder cases, this may be relieved by such drugs as antipyrine or phenacetin, in 10 grain doses, together with the local application of hot, dry cotton wool pads, or medical diathermy may be used. The application of the galvanic current is also effective in some cases, as is ionisation with quinine. In the more severe cases, bromides and chloral, or other more powerful hypnotics, are called for. Morphine should be avoided as far as possible, but should not be withheld in the extreme forms of the affection.

When the eruption has subsided, glycerine of atropine painted on and covered by hot, moist compresses is useful, and counter-irritation over the spine in the region of the affected nerve, either by a mustard plaster or blister, will allay the symptoms. Small doses of X-rays to the affected area sometimes produce considerable relief.

HERPES FEBRILIS

This is a condition to which some people, and especially children, are prone whenever they develop a slight febrile attack or even a slight cold.

Ætiology.—The disease is produced by a filter-passing virus, which, when injected into rabbits, produces a fatal form of encephalitis, and is closely related to the virus of encephalitis lethargica.

Symptoms.—The lesions consist of small groups of vesicles, on an

inflamed base, which come out chiefly in the neighbourhood of the mouth. They are irregularly distributed, have no relations to any nerve trunks, and are generally bilateral. They disappear in the course of a week or so, after crusting over, and leave no scars. In one type, seen especially in children, recurrent attacks occur on the cheek, often at regular intervals and without any special cause. These attacks also clear up and leave no scars. A recurrent type is also found affecting the buttocks in adults.

Treatment.—A bland protective ointment, such as zinc cream or Lassar's paste, is all that is required.

HERPES PREPUTIALIS

This is the name given to small crops of two or three to half a dozen or more small vesicles which sometimes appear on the under surface of the prepuce. The vesicles quickly rupture and leave behind pinhead-sized ulcers which are painful. There is no tendency for these ulcers to increase in size. This latter feature helps to differentiate them from both syphilitic ulcers and soft sores.

Treatment.—This is the same as for Herpes Febrilis.

D.—INFLAMMATORY DERMATOSES OF UNKNOWN ORIGIN

In this group are included certain dermatoses with well-defined characters which entitle them to be considered clinical entities, but whose ætiology is entirely obscure. The following diseases are included under this heading: psoriasis, parapsoriasis, pityriasis rubra pilaris, lichen planus, lupus erythematosus, sclerodermia and sclerema neonatorum. It must not be assumed that because these conditions are grouped together that they have any relationship to one another.

PSORIASIS

A very common condition characterised by the presence of red, scaly papules and patches of characteristic appearance on various parts of the body and unassociated with any disturbance of the general health.

Ætiology.—The disease frequently begins towards the end of the second decade, and is not infrequently seen in children from about 7 years of age and upwards, but is very rare in small children. Both sexes are equally affected. On the other hand, the first attack may occur in advanced age. It has been attributed to parasitic agencies, toxins of bacterial and metabolic origin, and to neuropathic causes, but there is very little evidence to support any of these views. There is no doubt that in some cases a strong family history can be made out.

Pathology.—Histological examination shows a great overgrowth of the epithelium, with downward growth of the interpapillary processes, and corresponding elongation of the papillæ. The horny layer is badly formed (parakeratosis), and collections of leucocytes can be found between the horny cells. There is a cellular infiltration around the papillary vessels and those of the subpapillary layer.

Symptoms.—The malady is a chronic one and may come and go throughout life. Usually attacks occur at quite irregular intervals, but

in some cases they may appear at definite seasons—some appearing in the summer, others in the winter. The extent also varies greatly in different cases, some only having a few patches, others being covered with lesions.

The sites of predilection are the extensor aspects of the limbs—especially of the elbows and knees—the trunk—both back and front, but especially the waist region, the scalp and, more rarely, the face, nails and palms and soles.

The lesions begin as pinhead-sized papules, and are from their very beginning surmounted by a small silvery scale. The individual lesions usually spread centrifugally and may eventually attain great size. Usually, however, they join with other patches and so form plaques, which may, for instance, cover the whole back in one continuous sheet. The same type of scaling persists even in the largest patches, though in chronic treated cases the surface of these patches may appear to be highly polished; on scratching, however, with a sharp instrument the silvery scales are immediately apparent. The whole mass of scales can, with care, be removed in one continuous sheet, and underneath is found a shiny, dry red surface which, on examination with a lens, shows the dilated papillary vessels as tiny red points.

The arrangement of the lesions varies. In some cases the body and limbs are studded with lesions the size of a small pea or a threepenny-piece (*psoriasis guttata*); in others the lesions are larger (*psoriasis nummulata*); in some the centre of the lesions clears up, leaving rings (*psoriasis circinata*), and the rings may run together, forming gyrate figures (*ps. gyrata*). Occasionally the crusts are very thick (*ps. rupioides*), and this is especially the case on the scalp, where the hairs prevent the scales from falling off.

In some cases the lesions remain small and confined to the follicles (follicular *psoriasis*), and these may occasionally group into patches. They may also come out along scratches on the skin. When the nails are affected, either small pinhead-sized pits may be produced, or the whole nail may be forced up by lesions occurring in the nail bed, the nail eventually breaking up and thick masses of scales being found beneath it. The palms and soles are less frequently involved, but when they are affected circumscribed red patches form, associated with scaling and fissuring in the deep folds. The mucous membranes are not affected.

The lesions vary from a pale to a dark red in colour, and on clearing up usually leave little or no pigmentation, though in very chronic patches, especially on the legs, some pigmentation may remain for a time.

There are usually no subjective sensations, but occasionally itching is present. The general health is not affected.

Diagnosis.—This disease may resemble the secondary *papulo-squamous syphilide*. It differs, however, from this condition in the fact that the lesions are scaly from the start; that when the scales are removed no infiltration can be felt, and that the surface left is smooth, dry and studded with numerous small red points; that pigmentation is generally absent or little marked; that the lesions are mainly distributed on the extensor aspects of the limbs, and that the scalp may be extensively involved without loss of hair; and that other signs of syphilis, such as general adenitis and involvement of the mucous membranes, are not present. The Wassermann reaction and the effect of treatment will generally confirm a clinical diagnosis.

In *seborrhœic dermatitis* the scales are greasy, the patches spread by aggregation of follicular papules, and the scalp, face and centre of the chest and back are chiefly affected. The lesions respond quickly to sulphur, which is not the case with psoriasis.

In *eczema* itching is marked, when the scales are removed a moist surface is left, and the lesions are made up of aggregation of papules and papulovesicles.

In *pityriasis rosea* the scaling is usually in the form of a collarette, the lesions are of a pale pink colour, and the limbs are little affected, especially below the elbows and knees.

In *lichen planus* some typical papules can almost always be seen, the lesions have a characteristic lilac or purple colour, the flexor aspects of the limbs are most involved, and itching is generally intense.

Treatment.—Internal treatment is considerably employed, but it is difficult to estimate its value. Arsenic is the most valuable drug, and should be given in increasing doses up to the limit of tolerance, but should be entirely discarded if no effect is produced. Fowler's solution, ℥ iii, t.d.s. and upwards, and pil. asiatica are chiefly employed. Recently mercury-salicyl-arsenate (enesol) has been used by intramuscular injection with success. Arsenic should not be given when lesions are coming out rapidly. In these cases salicin, gr. xv, t.d.s., and thyroid extract, gr. i, t.d.s., have been recommended by Crocker and others. Lately emulsions of sulphur and colloidal sulphur have been given with good results.

Local treatment is the most efficacious, and chrysarobin gives the best results, but is messy, stains linen permanently, and is liable to set up a severe dermatitis if used carelessly. It is best applied in 5 per cent. to 10 per cent. ointment rubbed into the patches daily, after the scales have been removed in a hot bath with the aid of soft soap.

If this treatment is carried out thoroughly for 3 or 4 weeks the patches will disappear. This treatment is best carried out in hospital or in a nursing home, and is not suitable for out-patient treatment. Pyrogallic acid ointment 10 per cent., oil of cade ointment 20 per cent., or an ointment consisting of ac. carb. 2 per cent., ac. salicyl. 3 per cent., soft soap 4 per cent., and sulphur 5 per cent. may be used. If the patches become inflamed they are best treated temporarily with linimentum calaminæ. Isolated resistant patches may be treated by a pastille dose of X-rays, but this cannot be often repeated. For the scalp, the crusts should be removed with soft soap, and the pyrogallic or sulphur and carbolic acid ointment recommended above applied. This latter ointment is useful in psoriasis of the nails, after the nail has been cut away and the scales removed.

PARAPSORIASIS

This is a term applied to certain rare forms of resistant erythematous-squamous lesions which occur on the body. Three types are recognised—(1) parapsoriasis en gouttes, (2) parapsoriasis en plaques, and (3) parapsoriasis lichenoides.

Ætiology.—Nothing is known of the ætiology of these conditions.

Symptoms.—*Parapsoriasis en gouttes* occurs as pea-sized or slightly larger red spots, covered by fine branny scales, chiefly on the upper part of the trunk.

Parapsoriasis en plaques occurs as symmetrical patches, oval or linear, of pale yellow or red colour, with a shiny surface or covered by fine scales, and occurring chiefly on the legs, thighs and lower trunk.

Parapsoriasis lichenoides forms a reticular pattern, chiefly on the extensor aspects of the upper limbs. The lesions are red or purplish in colour and the surface is either shiny or covered with fine scales.

Treatment.—These cases are very resistant to treatment, but should be dealt with on much the same lines as psoriasis.

PITYRIASIS RUBRA PILARIS

This is a rare disease characterised by the appearance of follicular papules, with horny spines, which tend to involve the whole cutaneous surface and eventually produce a generalised dermatitis resembling pityriasis rubra of Hebra.

Ætiology.—This is very obscure. It is thought by some observers to be a follicular form of psoriasis, but at present there is no conclusive evidence. The disease occurs in both sexes and at varying periods of life, but sometimes in the very young.

Symptoms.—The lesions are of two types: red follicular papules with horny spines, which are chiefly seen on the extensor aspects of the limbs, and especially on the dorsum of the hands and fingers; and red scaly plaques or sheets, which involve the scalp, face and trunk. Either of these types may predominate. Where the former type occurs the skin presents the appearance of a nutmeg grater. Hyperkeratosis of the palms and soles develops, with fissuring of the deeper folds, and the nails become pitted and brittle. Ectropion followed by conjunctivitis may occur. The mucous membranes usually escape. The malady does not seriously affect the general health, and subjective symptoms are usually absent.

Treatment.—No specific treatment is known. Thyroid extract has been recommended, but the results are very uncertain. Bran and alkaline baths, followed by inunctions of ac. salicyl., grs. x, glycer. amyl., adip. lanæ hydros., āā ʒss., seem to give the best results.

PITYRIASIS ROSEA

A widespread eruption of pinkish macules and papules of round or oval outline, with branny scaling, which does not usually extend to the periphery of the lesion.

Ætiology.—This is still obscure. It was originally thought to be of parasitic origin, probably owing to the resemblance of the lesions to ring-worm, but no definite parasite has been discovered. It is possible that it may be of the nature of an acute exanthem, as it occasionally has a sudden onset with slight fever and malaise. One attack is said to confer immunity, though this is not absolute, and it seems to occur at times almost in epidemic form. It has been thought by others to be a toxic eruption. The disease occurs chiefly in children and young persons, but no age is exempt.

Symptoms.—The eruption usually comes out suddenly, and the onset may, though this is not usual, be accompanied by slight fever, malaise and sore throat. In some cases the general outbreak is preceded by the appear-

ance of a single patch, the "herald" patch, which may appear a week or 10 days before the general eruption. The lesions are usually most profuse on the trunk and central portions of the limbs, the distal parts of the latter escaping. The face, neck and scalp may be affected, but this is not common.

The lesions are pinkish macules or papules, mainly macules, which vary in size from a lentil to patches a couple of inches across. They tend to be arranged in lines parallel to the ribs, and the larger patches are oval. When the lesions reach the size of a pea, central scaling commences, and as the lesions grow the scales tend to form a collarette, with the free edge directed towards the centre. The colour of the portion within the scales changes to fawn and eventually returns to the normal skin tint. Sometimes pinhead-sized follicular papules of skin colour are seen among the lesions in considerable numbers. In rare cases vesicles and bullæ form.

Subjective symptoms are usually absent, but sometimes itching is a prominent feature. The rash usually lasts about 4 weeks and then disappears, but it may persist for several months.

Diagnosis.—Seborrhœic dermatitis is distinguished by its greasy scales and by its distribution; secondary syphilis, by the presence of other syphilitic lesions; and ringworm, by the small number of lesions, their asymmetry, and the presence of fungus in the scales.

Treatment.—No internal treatment is known to affect the disease. In the early stages a simple coal tar and lead lotion can be used, as this allays itching if present. Once the rash is fully developed a daily warm bath, followed by the application of 3 per cent. salicylic acid in linimentum calcis, will usually cause the lesion to disappear. If there is fever the patient should be put to bed.

LICHEN PLANUS

An intensely itchy eruption characterised by the presence of angular papules of pinkish or lilac colour tending to be localised in special areas.

Ætiology.—The disease occurs chiefly in adult life and is very rare in young children. Two views are held as to its ætiology. By some it is thought to be of nervous origin, following shock, mental anxiety, worry, etc. It is true such a history is often obtainable, but Graham Little has pointed out that it has not appreciably increased as a result of the late war, which might have been expected if such was the main factor in its production. The other view is that it is of toxic origin, but there is no direct evidence on this score.

Pathology.—The microscopic anatomy of the papules is very characteristic. There is a circumscribed, dense, round-cell infiltration in the upper part of the dermis beneath the papule, and the epidermis is much thickened. The papillæ are flattened out. The granular layer is irregularly thickened and there is a hyperkeratosis, most marked at the orifices of the hair follicles and sweat ducts.

Symptoms.—The most common variety is the *localised type*. The lesions are chiefly found on the flexor aspects of the forearms and wrists, the inner aspects of the thighs near the knees, and on the front of the shins. The trunk, especially the lower part, the palms and soles, and the penis are also

occasionally involved. The mucous membrane of the mouth is frequently attacked. The lesions on the skin are discrete, lentil-sized papules, raised sharply from the skin, with polished shiny surface and usually of lilac colour. They have a curious and typical angular outline, due to the fact that they are bounded by the fine lines of the skin, and sometimes they are definitely umbilicated. Frequently the papules are arranged in lines along scratch marks. Occasionally patches are formed by the aggregation of papules and resemble rather closely patches of psoriasis. On the palms the lesions are generally circular, vary in size from a pea to a threepenny-bit, and the horny layer over them is much thickened.

In the mouth irregular dead white patches are found, usually on the tongue or inner aspect of the cheeks.

Several other types of lichen planus are seen. In one variety the lesions form rings and gyrate figures (*lichen planus annularis*), while in another atrophy occurs (*lichen planus atrophicus*). In a large number of cases the horny layer is much thickened (*lichen planus hypertrophicus*), and this is especially seen on the legs, where warty patches occur (*lichen planus verrucosus*). Occasionally the lesions are arranged in a single line, sometimes following the course of a nerve (*lichen planus linearis*), and very occasionally bullæ and vesicles may occur. Rarely cases are met with in which the papules are few in number, and very much hypertrophied, forming dome-shaped tumours, which itch intensely (*lichen obtusus*).

Another variety is an *acute generalised type* in which a large number of lesions are scattered diffusely over the trunk and limbs. In this type the papules are pale pink in colour and not so raised as in the chronic forms. Even in these cases the face and scalp almost invariably escape.

In association with the above-mentioned lesions small groups of follicular papules with horny spines may be found. The same condition is sometimes found independently of lichen planus and has been called *lichen pilaris* or *spinulosus*. Whether these latter cases have the same origin is still unsettled.

Lichen planus lesions are almost invariably accompanied by intense itching and often by marked neurotic manifestation, but otherwise the health remains good, though slight fever may accompany the acute cases.

The disease runs a very chronic course and is sometimes very resistant to treatment.

Diagnosis.—This is usually easy, as the lesions are very characteristic. The diagnosis from psoriasis has already been dealt with. From *lichenification* (*lichen simplex chronicus* of Vidal), which is produced by friction on the skin, the diagnosis is made by the fact that the latter only occurs in circumscribed patches, and that the typical discrete papules of lichen planus are absent.

Treatment.—In the acute generalised cases rest in bed is essential, and it is of the greatest service in chronic cases, materially shortening their course. Arsenic is looked upon as a specific, but may require to be pushed; salvarsan has been recommended by some authors. As in psoriasis, arsenic is not advised in cases in which the eruption is coming out, these cases doing best on mercury; liq. hydrarg. perchlor., ʒi, t.d.s. If the irritation is very bad, bromides or some hypnotic at night may be required, and for this symptom lumbar puncture has been recommended.

For local treatment anti-pruritic lotions and ointments are required; of these ichthyol, oil of cade, coal tar, carbolic acid and menthol are most useful.

For the hypertrophic patches, ac. salicylic plaster, followed by X-rays or CO₂ snow, is the most satisfactory method of treatment.

LUPUS ERYTHEMATOSUS

An inflammatory condition of the dermis, usually chronic but occasionally running an acute course, characterised by the presence of circumscribed red patches, with or without adherent scales and which on recovery leaves scars.

Ætiology.—This is still unknown. It has for many years been thought to be due to toxins of the tubercle bacillus and is sometimes associated with tuberculosis, but cases occur in which this disease cannot be traced. Lately a good deal of attention has been called to focal sepsis as a cause, but the evidence is no more conclusive than for tuberculosis. It is thought that it may be produced by more than one variety of toxin, or that it may be due to a specific organism as yet undiscovered. The disease is chiefly found in middle age, but may begin before the age of 20. It is more frequent in women.

Pathology.—The chief change in the skin is an infiltration in the neighbourhood of the vessels of the dermis with round cells, which may destroy the hair follicles and sweat ducts. In the epidermis there is a hyperkeratosis, which is especially marked at the follicular openings, so that horny plugs are formed.

Symptoms.—Two main types are seen—(1) The non-scaly or erythematous, and (2) the scaly.

1. *The erythematous type.*—This is less frequent and has a greater tendency to be generalised. It may run an acute course or may develop into the scaly type. The lesions are chiefly seen on the cheeks and form circumscribed disk-like lesions, raised and slightly infiltrated and of a pale-red to a purplish-red colour. These often show patulous follicular openings on the surface. They may also occur as diffuse flat non-infiltrated sheets of redness. This type is very apt to be associated with lesions in other parts of the body, particularly the backs of the hands and fingers, the arms and forearms, the chest, neck and ears. Occasionally an almost universal eruption appears. The patches may sometimes become bullous and hæmorrhage may occur into the bullæ. These disseminated cases may be associated with acute visceral diseases, such as pneumonia, pleurisy and nephritis, and even in the absence of these high fever may be present. Usually in this type of case, if the patient survives, the eruption clears up without much scarring.

2. *The scaly type.*—This is by far the commonest variety, and is generally very chronic and localised, but may occasionally be acute and generalised. The lesions are chiefly seen on the nose, cheeks, ears and scalp, but are not uncommon on the backs of the hands. They are very apt to be distributed symmetrically in the shape of a bat's wing on the nose and two cheeks. The lesions are usually irregularly shaped red patches, often sunk below the surface of the skin, and covered with greyish scales, which are extremely adherent. When removed horny plugs are seen to penetrate into the epidermis, and when the patches clear up a depressed scar is left, often with numerous pits on its surface. When the scalp is attacked the hair is lost permanently. The

mucous membranes may be attacked, the most frequent sites being the vermilion border of the lips and the palate.

Pain sometimes occurs in the patches and sometimes they itch, but generally no local sensations are present. The patient's health is usually below par, and there is often considerable neurosis, but severe constitutional symptoms are usually absent.

The course is exceedingly chronic, the patches often persisting for years in spite of treatment.

Diagnosis.—The condition is differentiated from *lupus vulgaris* by the absence of nodules, the symmetry of the lesions, the absence of ulceration and the age of the patient; from *erysipelas*, by the slowness of the spread and the absence of high fever; and from *erythema multiforme*, by the chronicity of the lesions and the presence of destructive effect on the skin shown by scarring.

Treatment.—The acute erythematous cases should be kept in bed and complications treated. All possible sources of focal infection should be removed. The drug which appears most to influence cases is quinine, which should be given in full doses. Local treatment is not usually required in the acute erythematous cases.

In the chronic scaly cases, quinine and general tonic treatment are indicated. Recently good results have been obtained by the intravenous injection of gold compounds, such as krysolgan, triphal or sancocrysin. Rest in bed is always beneficial, and the patient should not be allowed to go out in a strong wind or in the hot sun, as these aggravate the condition.

Local treatment is chiefly directed to removal of the scales and the production of a mild inflammatory reaction in the patches. For the former *ac. salicyl.* ointment, 3 to 5 per cent., or plaster, 5 to 10 per cent., may be employed. For the latter 5 to 10 per cent. pyrogalllic acid, painting with pure carbolic acid, or applications for a few seconds of CO₂ snow. Ultra-violet light has proved useful in some cases.

SCLERODERMIA

This is a condition of hardness and rigidity of the skin, caused by the overgrowth of fibrous tissue, which is probably of inflammatory origin. It is met with in two forms—(1) Generalised sclerodermia, and (2) localised sclerodermia or *morphea*.

Etiology.—Nothing is known of the cause. It is chiefly a disease of young adult life and is more common in women than in men. It has been variously attributed to a tropho-neurosis, to alterations in endocrine secretion, to an endarteritis, and to a primary hyperplasia of the fibrous tissue of the skin.

Pathology.—There is an overgrowth of the fibrous tissue bundle in the dermis and subcutaneous tissue, with replacement of fat by fibrous tissue in the latter. There is also an exudation of cells around the vessels of the dermis, with some endothelial proliferation. The epithelium may be flattened by pressure and excess of pigment may be present.

Symptoms.—1. *Generalised sclerodermia.*—This condition may appear rapidly or slowly. In both cases a disturbance of the general health, such as fever, joint pains, neuralgia or itching, may precede or accompany the attack. Stiffness of the parts involved is often the first symptom, and this may spread

rapidly or slowly till it produces fixity of the joints, followed by progressive wasting of the muscles. Breathing may become difficult, owing to fixation of the skin of the chest, and taking of solid food may be prevented by the involvement of the cheeks and mouth. The skin appears swollen and glossy and is very hard; the deeper structures are fixed and the furrows of the skin disappear. The colour of the skin may be normal or waxy in appearance. The lesions are usually symmetrical and the mucous membranes may be affected. These cases may occasionally clear up spontaneously, but often end fatally.

Occasionally the disease begins in the hands. The skin is drawn tightly over the fingers, fixation of the joints occurs and atrophy supervenes, so that the fingers become pointed. This type is called *sclerodactylia*.

2. *Localised scleroderma or morphœa*.—In this type the lesions vary from the size of a pea to large patches involving almost all the back or front of the trunk. Patches may be pinkish in colour and raised, with a smooth polished surface and with a sensation of rigidity; or slightly depressed below the surface, very rigid and fixed, and often surrounded by a lilac border, and occasionally occurring in bands; or again they may be of dead white colour, with more or less irregular edges, and of normal consistence. This latter type is one of the forms of so-called *white-spot disease*.

These cases run a very chronic course, often of many years, and are resistant to treatment.

Diagnosis.—From *sclerema neonatorum*, by the age of the patient and the fact that this condition is confined to the subcutaneous fatty layer.

Treatment.—In generalised cases, the patient should be kept warm, and massage and hot air baths given. Cod-liver oil internally is of value. Thyroid extract is largely given in all varieties, but its action is very uncertain. In *morphœa*, fibrolysin injections have been given with success. X-rays are claimed to be beneficial. Treatment, however, is unsatisfactory.

SCLEREMA NEONATORUM

This condition has no relationship to the foregoing. It occurs in newly-born infants, and is characterised by hardening of the subcutaneous fatty layer in certain parts of the body.

Ætiology.—It has been attributed to hardening of the fat, owing to lowering of body temperature and to a low percentage of olein of the fat. There is evidence of a deposit of crystals in the tissues, and of a well-marked proliferation of the reticulo-endothelial cells in the neighbourhood of these deposits, but the chemical nature of the changes is still undetermined.

Symptoms.—The affection usually begins within a day or two of birth. It occurs symmetrically and chiefly affects the calves, thighs, buttocks and back. The subcutaneous fat becomes very hard, and does not pit on pressure. The edges are well-defined. A certain number of cases die, but in the less severe cases the patches disappear in a month or two. A generalised hardening of the fat occurs all over the body in infants suffering from severe diarrhœa, but this condition appears to have no relation to that just described.

Treatment.—The child should be kept warm and given plenty of nourishment. Cod-liver oil is said to be very beneficial.

E.—THE LYMPHO-GRANULOMATA

These cases form a bridge between the inflammatory dermatoses on the one hand and the new-growths on the other. The lesions in many ways resemble the granulomata produced by bacteria, and in other ways resemble sarcomata. The following conditions are included—(1) Leukæmia cutis, (2) lymphadenoma cutis, and (3) mycosis fungoides. Possibly the sarcoids, including lupus pernio, should be included, but these have been previously considered.

LEUKÆMIA AND LYMPHADENOMA CUTIS

Symptoms.—In both these conditions itching may be a marked symptom; sometimes it occurs without any cutaneous lesions, while at other times very persistent urticarial or prurigo-like lesions are present. Hæmorrhages may occur into the skin, and in some cases exfoliative dermatitis is present.

The more characteristic lesions are, however, granulomatous infiltrations of the skin, which form tumours, either in certain localities or more or less all over the skin. In the former case the face is most affected, the tumours forming chiefly on the forehead, about the nose and on the cheeks, producing a leonine appearance. The lesions vary from a pea to an orange in size, and are usually of a dull purplish-red colour. Most of the cases recorded occur in lymphatic leukæmia, but a few have been reported in the myeloid cases. They also occur in lymphadenoma, but there is great difficulty in distinguishing aleukæmic leukæmia from lymphadenoma, unless the glands have been examined microscopically.

Treatment.—This has been dealt with in the articles on Leukæmia and Lymphadenoma (pp. 716 and 699).

MYCOSIS FUNGOIDES

A chronic inflammatory dermatosis with a tendency to form granulomatous tumours, which usually ends fatally.

Ætiology.—It is a disease of late middle life, and more common in men. Its cause is quite unknown, but it is probably an infective process and closely related to leukæmia, though no characteristic blood changes have been observed.

Symptoms.—In the early or premycotic stage the most frequent lesions are patches of redness and scaling, associated with intense itching. After a time these lesions become infiltrated and raised above the surface of the skin. Later, tumours appear in these patches, usually about the size of an orange, but not infrequently much larger. The epidermis over them gives way and a fungating mass is produced. These tumours are usually multiple.

Sometimes the initial lesion takes the form of an eczema, an urticaria or a dermatitis exfoliativa, but in all these cases itching is a prominent symptom. In other cases the tumours appear without any pre-existing dermatosis.

The course is slow, and the general health is affected first by loss of sleep and then by septic absorption. Practically all cases eventually terminate in death.

Diagnosis.—This may be very difficult in the premycotic stage. The itching and the persistence of the symptoms in spite of treatment, together with the age of the patient, will help in coming to a diagnosis.

Treatment.—The only treatment known to benefit these cases is X-rays or radium. Either of these will keep the lesions quiescent for a considerable time, but recurrence generally takes place sooner or later. Arsenic and antimony may also be given.

A. M. H. GRAY.

IV. TUMOURS OF THE SKIN

Tumours can be divided into epithelial and connective-tissue tumours, and each of these varieties into benign and malignant.

BENIGN EPITHELIAL TUMOURS

WARTS

These are benign epithelial tumours, characterised by an overgrowth of the prickle-cell layer, with or without hyperkeratosis, and produced by an infective agent, the nature of which has not been discovered. The following types are recognised :

1. *Verruca vulgaris*.—This is the common wart which is so frequently met with on the back of the hands, but may occur on the face and other parts of the body. The lesions are raised tumours, varying in size from a pinhead to a large pea, and are usually discrete, but may group to form larger swellings. They have a rough surface, rise sharply from the surrounding skin, and are skin-coloured. Histologically they show great hypertrophy of all the epithelial layers, with downward growth of the interpapillary areas, and a corresponding papillary elongation. They occur chiefly in children. They are inoculable from one spot to another, and from one individual to another.

Treatment.—Isolated lesions are best removed by the application of CO₂ snow for from 15 to 40 seconds, according to their size. They may be burnt away with glacial acetic, trichloroacetic, or nitric acid, silver nitrate or even the actual cautery. When very numerous, magnesium ionisation or X-rays are most satisfactory.

2. *Verruca plana juvenilis* are pinhead-sized warts, seen chiefly on the face and hands of children, though they are met with in adults. They have smooth, flat tops, and are usually very numerous.

Treatment.—They are best treated by touching with the galvanocautery, or by magnesium ionisation.

3. *Verruca plantaris*.—This is a wart which occurs in the centre of the ball of the foot, and has the appearance of a corn, because it is surrounded by a hyperkeratotic ring, and on account of the pressure on the foot does not stand up above the level of this ring. It is, therefore, often mistaken for a corn. It is usually extremely painful.

Treatment.—The most satisfactory treatment is by X-rays; a full pastille dose is usually sufficient; but occasionally larger doses are necessary, the surrounding zone being carefully screened. These warts may also be removed by salicylic acid plaster, followed by touching with acetic acid or by CO₂ snow.

4. *Verruca filiformis*.—These minute warts are usually about 1 mm. in

diameter at their base, with long filamentous processes. They are sometimes found on the face; but chiefly occur on the genitals, and around the anus. They frequently occur in very large numbers forming cauliflower-like growths. They are often seen in cases of gonorrhœa, and are sometimes known as *gonorrhœal warts*; but they may be present apart from this disease, and are probably due to some other infecting agent. In these warts there is very little overgrowth of the horny layer.

Treatment.—Locally antiseptic applications, such as 1 in 1000 perchloride of mercury in spirit painted on frequently, or silver nitrate 3 per cent. in sp. æth. nitros., will cause them to dry up, or they may be removed with the galvano-cautery.

5. *Keratoma senile.*—These so-called senile or seborrhœic warts are commonly seen on the face, back and chest of old people; but may occur in younger persons. They vary in size from a pea to a filbert, and are only slightly raised from the skin. They are soft to the touch, and have a slightly warty surface. Their colour varies from yellow to a deep black, and they may itch a good deal. The distribution is much the same as for seborrhœic dermatitis.

Treatment.—Washing with soap and water, followed by the application of 10 per cent. ac. salicyl. ointment will often remove them. Failing this, painting with trichloroacetic acid, freezing with CO₂ snow, or a pastille dose of X-rays should be employed.

ACANTHOSIS NIGRICANS

This is a rare condition in which warty pigmented growths appear on the neck, axillæ, groins, umbilicus, and flexures of the limbs and on the face. These growths often fungate and suppurate, especially in moist areas. In addition areas of pigmentation and scattered warty growths may occur. The mucous membrane of the lips, cheeks and tongue may be affected. In a large proportion of cases abdominal malignant growths have been found; but in other cases no such complication exists. The nature of the condition is not understood.

Treatment.—No treatment is known to affect the condition.

THE DYSKERATOSES

MOLLUSCUM CONTAGIOSUM

In this condition small tumours appear on the skin which, like the warts, are of infective origin, though no organism has yet been isolated. They differ from warts, not only in clinical characters, but in the peculiar degenerative changes which occur in the process of horny cell formation.

Pathology.—The most striking feature in a section is the presence between the Malpighian and horny layer of large cells containing large transparent oval bodies. These are known as "psorosperms," and at one time were thought to be coccidial bodies, but are now considered to be degenerations of the cell protoplasm.

Symptoms.—The lesions consist of small lentil- to pea-sized bodies of a white or pinkish colour, with a smooth glistening surface. They may

appear anywhere on the skin. They are dome-shaped, and have a central pit, in the floor of which the thickened horny layer can be seen. Not infrequently they become inflamed.

Treatment.—By taking a sharpened match, and introducing it into the central depression, the whole horny mass can be forced out, and if the cavity be painted over with pure carbolic acid a cure will result.

DARIER'S DISEASE

This is a very rare condition of the skin usually seen in young adults in which an eruption of follicular papules develops on the face, scalp, abdomen, back, and the flexor aspects of limbs. The lesions run together and form warty-looking masses. The disease is slowly progressive, and the lesions are resistant to treatment, but the general health is not affected.

Microscopic examination shows similar changes to those seen in molluscum contagiosum, namely, an irregular hyperkeratosis with formation of "psorosperms" in the region of the granular and Malpighian layers of the epidermis.

Treatment.—This consists of baths and the application of keratolytic agents, such as salicylic acid.

PAGET'S DISEASE OF THE NIPPLE

This is a chronic affection which usually develops around the nipple in middle-aged women, but has been described in other parts of the body and in men. It is seen as a sharply defined, red, oozing area involving the nipple, the areola, and the skin around for a short distance, and is almost always unilateral. The whole area has a distinct parchment-like induration. The nipple becomes retracted, and eventually disappears. The condition is associated with carcinoma of the breast, and whether it is primary or secondary is still a matter of dispute.

In this condition, as in the two diseases just referred to, "psorosperms" are seen under the microscope. The surface horny layer is mostly lost, and the deeper layers of the epidermis are much hypertrophied and œdematous, but show no obvious epitheliomatous proliferation.

Treatment.—Amputation of the breast is the only treatment that can be advised.

MALIGNANT EPITHELIAL TUMOURS

RODENT ULCER

A slowly growing epithelioma usually single, but sometimes multiple, which may cause considerable local destruction of tissue but does not form metastases.

Pathology.—This variety of epithelioma is usually described as a basal-cell epithelioma. In section epithelial processes are seen penetrating into the underlying dermis and subcutaneous tissue; but the processes are bounded by a regular basal layer of cubical cells, and although degeneration cysts may form in these processes no cell-nests are formed.

Symptoms.—The lesions chiefly occur in old people; but this is not

always so. They also rarely begin anywhere but on the face, and then chiefly in the neighbourhood of the eye, or on the nose or cheek. At first a small raised white nodule appears, with small vessels coursing over it. Then, as it spreads, an ulcer forms in the centre, but the raised intensely hard white border persists. If not treated a great deal of tissue destruction occurs; the nose may be destroyed, or the antrum perforated, and the whole of the nasal cavities opened up. In advanced cases practically the whole face is destroyed. Some cases, however, remain superficial, spreading slowly, the older parts healing as the lesion spreads. Multiple lesions are not very rare.

Benign forms are also recognised. In one the lesions are pea-sized or slightly larger nodules, scattered over the face, and of the same type as the early lesions referred to above. Sometimes they undergo cystic change. They were described by Brooke under the name of *epithelioma adenoides cysticum*. Another benign type is seen in which multiple walnut-sized tumours form on the scalp. A third type occurs in the form of multiple psoriasiform patches on the trunk and has been named by Graham Little *erythematoid benign epithelioma*.

Diagnosis.—This can always be made in cases of doubt by microscopic examination.

Treatment.—Excision is the best treatment when possible; but excellent results are obtained by radium. CO₂ snow has been advocated for early cases, and the results obtained are excellent. In advanced cases, which are unsuitable for surgical treatment, scraping followed by the application of arsenic paste has given good results, and diathermy is also useful.

SQUAMOUS EPITHELIOMA

In this condition rapidly growing tumours form, which ulcerate and cause local destruction of tissue, and also cause secondary glandular involvement. It is chiefly a disease of old age.

Pathology.—Sections show an irregular proliferation of the Malpighian layer, with the formation of cell-nests, and the limiting basal layer is absent.

Symptoms.—The lesions begin as nodules, much like those of rodent ulcer, but they spread much more rapidly and either form irregular deep cut ulcers, without the characteristic edge seen in rodent ulcer, or else they become raised and form mushroom or cauliflower-like growths. The glands are soon involved, and general dissemination may occur. The condition may sometimes supervene on pre-existing non-malignant conditions. It may commence in a keratoma senile, in the warty conditions which occur in cases of atrophy of the skin due to exposure to tropical sun, on an old lupus scar, on X-ray dermatitis, in xeroderma pigmentosa, in arsenical keratoses and in tar molluscum.

Treatment.—This is purely surgical, and consists of erosion of the local growth and of the glands draining the area concerned. In the case of epithelioma complicating lupus vulgaris, however, secondary glandular involvement does not appear to occur, and local destruction with arsenic paste, or by diathermy, gives even better results than excision.

TUMOURS OF THE APPENDAGES OF THE SKIN

MILIUM

In this disease pinhead-sized yellowish-white bodies are seen in the skin of the face, chiefly on the cheeks, eyelids and forehead. They are often very numerous. They can be shelled out, and are found to consist of a whorl of epithelial cells. Their origin is unknown, but they are probably derived from the lanugo hair follicles.

Treatment.—These tumours can be destroyed by electrolysis.

SEBACEOUS CYSTS

These are painless cystic swellings chiefly found on the scalp, face, ears, back and scrotum. They vary in size from a pea to an orange. When incised they are found to be filled with cheesy matter. They are either due to blocking of the sebaceous duct, or according to some authorities they are of embryonic origin. True *dermoid cysts* of the skin are also found.

Treatment.—Excision is the most satisfactory method of treatment.

ADENOMA SEBACEUM

A symmetrical eruption of pinhead-sized, bright red papules, of congenital origin, on the face. It commences very early in life, and is often associated with mental defect—in fact cases are most often seen in asylums. The lesions are distributed chiefly over the nose and cheeks, and consist of hypertrophied sebaceous glands and numerous capillary vessels.

Treatment. The lesions can be destroyed with the galvano-cautery, by electrolysis or by diathermy.

Tumours of the sweat glands and ducts are so rare as to need no description here.

CONNECTIVE-TISSUE TUMOURS

KELOID

This is a fibrous tumour developing in a scar. The mere overgrowth of a scar is sometimes referred to as a *hypertrophic scar*, while the term keloid is limited to those cases in which the tumour extends beyond the original limits of the scar. In this latter condition processes often grow out in all directions like tentacles, and also in some cases the condition appears to start spontaneously from the normal skin; but there can be little doubt that some small abrasion was present. Small keloids often appear after acne vulgaris, varicella and other dermatoses which lead to scarring. There can be little doubt that this fibrous overgrowth is due to some chronic bacterial infection of the wound—probably a staphylococcal infection.

Treatment.—The best results are obtained by radium and X-rays. With the latter, pastille doses given at about two months' interval on two or three occasions give satisfactory results.

FIBROMA—MOLLUSCUM FIBROSUM

Hard fibromata of the skin are rare, and usually occur in pear-sized nodules scattered about the skin. Soft fibromata are common, and are met with as small pedunculated tumours, chiefly on the trunk. They may occur in large numbers, and are then described as molluscum fibrosum. In this condition the tumours vary in size from a small pea up to several inches in diameter. Not only the skin but the mucous membranes may be the seat of these tumours. At times they form huge dependent unshapely masses, which completely disfigure the part from which they arise; this condition is called *dermatolysis*. Not all the tumours are pedunculated—as some are sessile—but all have the same softness. Some definitely surround nerve trunks, and it has been thought that they all develop in connection with the nerve fibres; hence they are often called *neuro-fibromata* or *plexiform neuromata*.

In some cases true neuro-fibromata and molluscum fibrosum lesions occur in combination with pigmented spots about the body. This syndrome is called *Recklinghausen's disease*, and is sometimes associated with mental disturbance.

Treatment.—Nothing can be done except surgical removal of the tumours, and this is only occasionally necessary.

LIPOMATA

These are soft freely movable lobulated tumours in the subcutaneous tissue, and may be single or multiple. One variety is very painful and associated with general adiposis, and is referred to as *Dercum's disease* (p. 177).

Treatment.—Excision is the only treatment.

MYOMATA

Small multiple tumours of the size of a pea are sometimes found which have the structure of leiomyomata, and arise from the arrectores pili muscles. The lesions are often numerous, grouped and painful.

Treatment.—The cautery, or excision, is the only treatment.

MULTIPLE IDIOPATHIC SARCOMA OF KAPOSI

This is a curious condition chiefly seen in old people, and generally in the natives of Eastern European countries; but cases have arisen *de novo* in this country. The lesions occur chiefly in the region of the ankles, but have also been found on the hands and on the trunk. They are irregularly shaped red plaques raised from the skin, and of firm consistence. Histologically they consist of an overgrowth of fibrous tissue with dilated blood spaces. Whether this condition is of inflammatory origin, or is a species of *nævus* is as yet undecided. The condition does not affect the general health.

Treatment.—No treatment is known to affect the condition.

SARCOMATA

Both round- and spindle-celled sarcomata have been found arising in the skin, but are rare. They may be single or multiple, of any size, sessile or pedunculated, and are usually of a purplish-red colour. They tend to break

down and produce fungating ulcers, and run a rapid course ending in death unless removed in the early stages.

Treatment.—This is purely surgical.

NÆVI

This term should be applied only to certain new formations of congenital origin; but in practice certain other conditions have been included. They fall into four classes—(1) Vascular nævi; (2) lymphatic nævi; (3) pigmented nævi; and (4) hyperkeratotic nævi.

VASCULAR NÆVI.—There are two chief varieties, the capillary and the cavernous nævi.

Capillary nævi.—These nævi are essentially dilatations of the capillary vessels of the papillary and subpapillary layers of the dermis. They form flat red patches of varying size. They may be small pea-sized lesions, or they may practically cover the whole body, including the mucous membranes. When they occur in large patches they are called *port-wine stains*.

The lesions are usually not raised and not infiltrated, the only change being in the colour of the skin, which is red or purple in the affected areas. Sometimes, however, thickenings occur irregularly throughout the patches. On examination with a lens the capillaries can often be seen. These nævi are either present at birth or appear shortly afterwards. They tend to get paler as age advances, but rarely disappear.

Treatment.—These cases are very difficult to treat, especially the more extensive ones. CO_2 is useless, unless the application is sufficiently long to destroy the skin. Radium, though sometimes successful in removing the nævus, is inclined to produce atrophy and telangiectases in its place. The best hope in disfiguring cases rests with excision and plastic surgery, though some fair results have been obtained with diathermy.

Cavernous nævi.—These are soft or hard tumours, which appear as bright red sharply defined swellings raised above the level of the skin or as purplish indurations in the skin and subcutaneous tissue. The blood can usually be squeezed out of them by pressure. They consist of a fibrous stroma surrounding irregular blood spaces, the whole being more or less encapsuled. The tumours vary much in size and extent, some being as large as a cricket-ball or larger. Any part of the body may be affected, but they are frequent on the face and scalp, the lips and eyelids often being attacked.

Treatment.—Small tumours are best treated with CO_2 snow, one exposure of 15 to 30 seconds being sufficient to remove them. Larger tumours may be dealt with by repeated applications of snow, but they do better with multiple punctures with a fine galvano-cautery at dull red heat. In some situations excision is the best treatment, while radium can often be used with success. Electrolysis was formerly much employed, but is slow and has been superseded by the methods mentioned above. It is often advisable to abstain for a time from active treatment, as there is a tendency for the tumours to disappear spontaneously.

Stellate nævi.—These are not strictly nævi at all—that is, they are not congenital growths. The cause is not clear, but they may be degenerations or possibly traumatic dilatation of venules. The lesions consist of a central pinhead-sized dilatation of a venule, with a stellate arrangement of dilated

vessels running into it. They are seen chiefly in children on the face, but also occur in adults. It has been thought that insect bites may be a determining cause.

Treatment.—If the central vessel is destroyed by a fine galvano-cautery or by electrolysis the lesion will disappear.

LYMPHATIC NÆVI.—**Synonym.**—**Lymphangioma Circumscriptum.**

This occurs as a raised circumscribed patch of skin colour, which on close examination is seen to consist of closely grouped vesicles, varying in size from a pin's head to a lentil. There may be a few discrete vesicles surrounding the main patch. In some cases, too, the surface is warty. The patches appear at or soon after birth, but may come out later. Microscopic examination shows dilatation of the lymphatic vessels of the dermis, with or without epidermal hypertrophy.

Treatment.—Excision, cauterisation or treatment by radium are the three methods applicable.

PIGMENTARY NÆVI OR MOLES.—Nævi of this class are very numerous and vary considerably in type. They may consist of pigmented patches of varying size and various depth of colour from a pale yellow to a deep black. These may be associated with hairy growth. In other cases smooth lobulated pigmented tumours may occur on any part of the skin. Some cases have a rough, warty surface, while others are hairy. They may be quite small, no larger than a pea, or may cover large areas of the body, and have a distinct tendency to occupy segmental areas. They may appear at or soon after birth, or may occasionally develop later in life. The histological picture is characterised in all types by the presence of masses or columns of round embryonic cells in the dermis and also in the deeper layers of the epidermis. There is excess of pigment in the cells of the basal layer, in the adjoining Malpighian layer, and also pigmented wandering cells in the upper part of the dermis. The epidermal changes vary with the type of nævus.

There is a slight tendency for these pigmented moles to undergo malignant transformation into *nævo-carcinoma*, which has a high degree of malignancy, giving rise to rapidly generalised metastases.

Treatment.—It is best to leave pigment moles alone unless some definite indication for treatment is present. Free excision with grafting or plastic procedures is indicated in some disfiguring lesions, or in those liable to irritation from friction. CO₂ snow or electrolysis may be used in the case of the smaller tumours.

HYPERKERATOTIC NÆVI.—**Synonyms.**—**Linear Nævi; Ichthyosis Hystrix.**

In this type of nævus the lesions are arranged in lines or bands, usually on the limbs, and often appear to follow the course of certain nerves. They are frequently unilateral, though in the *ichthyosis hystrix* type they are frequently symmetrical. The lesions consist of thick horny plugs, which can be pulled out from depressions in the skin, and are closely packed together; sometimes great horns protrude from the skin. On microscopical examination an irregular hyperkeratosis is found, with alternating depressions and elevations.

Treatment.—This is very unsatisfactory. Salicylic acid plasters may be used to soften and remove the horny masses, and small areas can be excised or cauterised.

V. OTHER MORBID CONDITIONS OF THE SKIN

ANOMALIES OF PIGMENTATION

Pigmentation may be produced by the deposit of blood pigment in the skin, by the excessive production of melanin—the normal pigment of the skin, or by the deposition of such substances as silver, seen in poisoning by that substance.

Blood pigment is found after hæmorrhages have subsided and in congestive conditions.

Increase in melanin occurs in the pigmentary nævi already referred to; in certain internal diseases, such as Addison's disease, diabetes and exophthalmic goitre; and in pregnancy; after the ingestion of arsenic; and locally, after certain inflammatory conditions of the skin, such as sunburn, erythema ab igne, lichen planus and syphilis. It also occurs in a curious condition named vitiligo, the ætiology of which is obscure.

LENTIGO

This is the name given to *freckles*, which occur on parts of the body exposed to the sun in certain individuals. The lesions are so well known as to require no description.

Treatment.—This is purely preventive. The application of a greasy preparation, such as lanolin, to the skin before exposure to the sun will protect the face from an erythema; sunshades and veils, especially red or brown, are also useful.

CHLOASMA UTERINUM

This is a peculiar yellowish-brown pigmentation which occurs chiefly about the face in women who are pregnant, or suffering from some uterine disturbance. It occurs in ill-defined patches, chiefly on the forehead and on the abdomen. It disappears after the termination of pregnancy, or when the pelvic condition is rectified.

VITILIGO

This condition, also known as *leucoderma* and *melanoderma*, may occur at any age or in either sex. The ætiology is quite unknown, both toxic and tropho-neurotic theories having been invoked to explain the phenomenon, but very little evidence is at present forthcoming in favour of either view. It consists of patches of a dead white colour appearing in various parts of the body; they may be quite small, or may in rare cases completely cover the body. The edge of the patches is sharp, and the surrounding skin is hyperpigmented; the texture remains normal. In the white areas pigment is entirely absent, but no other histological changes can be observed. The patient's health is in no way affected, nor can any derangement of any of the organs of the body be made out in the majority of cases.

Treatment.—The only treatment which appears to have any effect is the repeated application of ultra-violet rays, either by the Kromayer lamp or by arc-light baths.

ALBINISM

This is a congenital condition in which there is complete absence of pigment in the skin and other epidermal structures. The hair is white, the eyes pink from absence of pigment in the iris, and the skin fails to pigment, even when exposed to the strongest sun.

ATROPHIES OF THE SKIN

Various conditions may cause atrophy of skin, particularly local inflammations, but under this heading certain atrophic conditions are dealt with that have not been considered elsewhere.

SENILE ATROPHY

Generalised atrophy of the skin occurs in old age. The skin becomes thin and loses its elasticity; irregular pigmented spots, small telangiectases and vascular cysts (de Morgan's spots) appear, especially on the face and trunk; wrinkles are very numerous; and the skin develops a yellowish colour. A generalised pruritus may occur. Senile warts are frequently found, and these may be the seat of a localised pruritus. They occasionally become transformed into squamous epitheliomata.

Treatment.—This is purely symptomatic.

STRIÆ ATROPHICÆ

These are bands of atrophic skin which develop in areas where the skin has been much stretched. They are seen best on the abdomen, **breast** and hips of women who have borne children. The lines when first formed are red in colour and about $\frac{1}{2}$ inch in diameter, but as they get older they become greyish-white. It is thought that they are produced by damage to the elastic fibres of the skin by stretching.

No treatment is required.

XERODERMIA PIGMENTOSA

This is a rare condition of the skin which is hereditary. The **ætiology** is quite unknown, but there is no doubt that light-rays play a part in the production of the lesions. The affection begins in infancy, and is characterised by the appearance on the face and backs of the hands of macules of yellow and brown pigmentation. The disease is slowly progressive, and in addition to pigmentation other signs of skin degeneration appear, namely, atrophic patches, telangiectases and warty growths. Later ulceration occurs and epitheliomatous tumours appear on the warty growths.

Treatment.—The patient should be protected from the sun's rays as much as possible. The warty growths can be removed and the ulcer treated antiseptically. Epitheliomatous growths can be checked by radium, but the cases always end fatally.

CONGENITAL CONDITIONS OF THE SKIN

Most of these, such as ichthyosis, the nævi and xeroderma pigmentosa, have been already considered. There still remains one condition which has not been alluded to, namely, epidermolysis bullosa.

EPIDERMOLYSIS BULLOSA

This is a congenital defect of the skin which renders it extremely sensitive to the slightest injury. In those affected, the slightest knock is sufficient to produce a blister. The disease is hereditary, and can often be traced to a considerable number of members of a family. The lesions usually appear first in early infancy, but occasionally they have occurred for the first time later in life. They vary much in degree. In some cases the lesions are slight and cause very little inconvenience, and no disturbance to the general health. In other cases the lesions are numerous, almost all parts of the body being affected at one time or another; teeth and nails develop badly, septic complications are often severe, and these cases usually do not live to adult age.

Treatment.—Nothing can be done except by prevention of sepsis and the antiseptic treatment of the lesions when once formed.

DISEASES OF THE HAIR

ALOPECIA

Loss of hair occurs in many diseases. It may fall out after acute illnesses, such as influenza and typhoid fever, in inflammatory conditions of the scalp, in secondary syphilis, and in dermatitis exfoliativa. It is also lost locally in scarring conditions, traumatic or inflammatory, as seen in lupus erythematosus or tertiary syphilis. A progressive loss also occurs in senile atrophy of the skin; this, however, may occur prematurely.

ALOPECIA PREMATURA.—**Ætiology.**—The disease is essentially one of the male sex, and usually begins at about the age of 20. The ætiology of the disease is not clear. Two factors appear to be present, heredity and seborrhœa of the scalp. It is quite clear that the latter condition by itself does not always produce baldness, but it appears to accelerate the loss of hair, as might be expected. Heredity seems to be important, especially in those cases where complete baldness occurs at an early age, and there is no doubt that fine hair is more liable to fall out early than is stouter hair.

Symptoms.—This gives rise to a very characteristic type of hair loss which is familiar to every one. The hair gradually gets thin on both temples and on the vertex, and by slow progression these thinned areas eventually meet, leaving the top of the head entirely bald or only covered by a fine down, while the sides and back of the scalp are covered normally. The progress varies very considerably in different individuals, some becoming completely bald in a year or two, while others still have a good crop of hair at 50.

Treatment.—This has mainly to be directed to curing the seborrhœa,

and the methods for doing this have been dealt with under that heading. Apart from this, avoidance of tightly fitting hats, and gentle massage with the fingers are the most appropriate remedies. Certain drugs such as pilocarpine, have been thought to have a stimulating effect on hair growth, and rubefacients, such as cantharides, are also much employed. The general health should receive attention.

ALOPECIA AREATA.—In this condition the hair falls out in patches, leaving smooth, shiny, bald areas. There is a general tendency for the hair to grow again.

Ætiology.—The malady affects both sexes and generally occurs in early adult life. It is probable that the disease is an inflammatory condition, but the nature of the irritant is unknown. A somewhat similar loss of hair can be produced by the administration of thallium salts, which lends support to the toxic theory. It was at one time thought to be due to an external parasite, but there is no evidence to support this view. It has also been thought to be of nervous origin, as damage to nerves has produced bald patches over the areas supplied.

Symptoms.—The disease may start suddenly or slowly. In some cases a large circular patch of baldness may occur in a single night, and in these cases the skin may be tender and reddened. Generally, however, a small bald patch appears, which spreads slowly, and other patches may subsequently arise, causing considerable loss of hair and a curious patchy condition of the scalp. Not only the scalp hairs but those of the beard, the eyebrows, axillæ and pubes may be affected, and in severe cases all the hairs of the body, including the eyelashes may fall out. In one type a band of hair may be lost extending from ear to ear around the margin of the scalp, either in front or behind the head or even in a complete circle.

In the patchy form, the individual patches are characteristic. The centre is usually completely bald and shiny, though new downy hairs may be seen. Around this a row of stumps may be observed. These are club-shaped, like a note of exclamation, being very thin as they enter the scalp and thicker above. When pulled out, a shrunken hair bulb comes out and the hair does not break as in ringworm. The zone outside the zone of stumps looks normal, but if the hairs are pulled upon many loose hairs may be detached.

Course.—This varies in different cases. Usually new hair grows fairly rapidly, and the patches cease to spread. The new hair is usually white when it first appears, but pigments later. In some cases, however, the patches progress as new hairs grow and this may continue for many months. In the band-form hair growth is usually much slower. In the generalised cases the prognosis is not so good, a large proportion losing the hair permanently.

Diagnosis.—This has to be made from ringworm and is generally easy. In ringworm the patch is scaly and covered by stumps, which break easily and have an irregular fractured end. Under the microscope the fungus can be seen.

Impetigo contagiosa of the scalp sometimes gives rise to bald patches. They are numerous, small and usually red in colour, and no stumps are seen.

Treatment.—The general health must be looked to and all possible sources of irritation removed. The teeth must be attended to, tonsillar sepsis treated, and errors of vision corrected. General tonic treatment

should be prescribed, and rest from overwork and worry ordered. Thyroid extract has been recommended, but in the writer's experience has sometimes made the condition worse.

Local applications which cause hyperæmia are of most value. Painting the patches with pure carbolic acid, iodine or blistering fluid, or rubbing in oil of turpentine are useful. Various antiseptic lotions, such as perchloride of mercury and resorcin, have been used with success. High frequency current and ultra-violet rays have given good results when other means have failed. If seborrhœic dermatitis is present it should be treated.

CICATRICAL ALOPECIA.—In this condition, also known as *pseudo-pelade* or *folliculitis decalvans*, progressive loss of hair takes place, and the scalp shows signs of atrophy or scarring. There is a progressive patchy loss of hair occurring over considerable areas of the scalp, and on examination inflammatory lesions are often present round the hair follicles. The denuded areas show obvious scarring, and hair does not regrow on the patches. The disease occurs chiefly in young adults, and though it does not usually lead to complete baldness, very disfiguring patches remain.

Treatment.—This consists in the application of antiseptic ointments and lotions, perchloride of mercury, resorcin and sulphur being the most useful, but no treatment is very efficacious.

HYPERTRICHOSIS

This is the term applied to an excessive growth of hair. It is usually confined to those cases in which a growth of stout hairs occurs in sites usually covered with lanugo hairs, such as the face in women. This may sometimes be very excessive, and the "bearded woman" and the "dog-faced man" are extreme examples, though the latter are often cases of hairy moles. The only conditions that the medical practitioner is likely to have to deal with are those in which stout and dark hairs occur on the chin and upper lip in women. The treatment consists in removal of the hairs by electrolysis, but considerable judgment is often required to decide whether a case is suitable for treatment. Electrolysis consists in passing a current of about 1 milliampere for a quarter to half a minute into the hair bulb by means of a fine needle attached to the negative pole of a galvanic battery. The hair then loosens and can be removed. It is important not to remove hairs too close to one another at the same sitting, or troublesome scarring will supervene.

A. M. H. GRAY.

VI. TROPICAL SKIN DISEASES

CRAW-CRAW

Definition.—A West African native name (kra-kra) applied indiscriminately to any itching, papular or pustular eruption of the skin.

Ætiology.—O'Neil claimed he found filarial embryos in an eruption which clinically resembled scabies. It is quite possible the subjects already had filarial embryos in their blood, and when he pared the tops of the

papules with a sharp knife some of the blood infected the smears. This would account for their presence in the papules. Recently, however, Scott Macfie has shown that filarial embryos (*Agamofilaria streptocerca*) are very common in the skin of West African negroes, and may be demonstrated in sections. There is no doubt that these are what O'Neil saw. Possibly they have nothing to do with the eruption.

Treatment.—Many of the so-called crawl-crawl cases are really a form of scabies, and respond quickly to sulphur baths. Castellani believes some of these cases are the same as coolie itch. This consists of an eruption of intensely itchy papules, converted by scratching into pustules and often into open sores. No acari are obtainable, however, and no burrows are seen. He advises a salicylic acid spirit lotion, followed by a β -naphthol ointment. Carbolic lotion improves some of the cases.

PRICKLY HEAT

Definition.—A form of miliaria, due to excessive sweating in hot climates.

Ætiology.—No organism has been isolated, and as the condition quickly disappears in a cold climate it is possibly purely a mechanical process—blocking of the orifices of the sweat glands by sodden cells of the stratum corneum.

Symptoms.—Most people are attacked shortly after arriving in the tropics. The eruption is very irritating, and causes a pricking sensation with great itching. The lesions chiefly occur on the trunk, but may also attack the arms and legs. The itching may become intolerable and render sleep difficult, if not impossible. The eruption consists of small watery vesicles and inflamed papules generally merged together, which feel like grains of sand. If the weather becomes cooler it tends to disappear, only, however, to return quickly in the hot weather.

Treatment.—The underclothes should be changed daily, as failure to do so seems to add to the irritation. Some recommend washing with fairly strong carbolic soap, or painting the patches with corrosive sublimate solution 1 in 1000. Rubbing with lime juice is recommended in the West Indies. After the bath some dusting powder, such as zinc oxide with boracic acid and starch in equal parts, should be employed. Sea bathing often seems to improve it, if not actually to cure it.

FURUNCULOSIS

Boils and similar pyogenic conditions are very commonly met with in the tropics. People are so often bitten by all sorts of insects that there is a constant source of infection, more or less, always present. The best treatment for boils is the same as at home, namely, an autogenous vaccine. If that does not succeed the patient should be sent home to a cold climate for a change.

Veldt sore (Barcoo rot) is another coccal infection, due to streptococci. A definite ulcer forms, very difficult to heal, and often lasting 3 to 6 months. Several sores may exist at the same time. Some of the sores may reach the size of half a crown.

Diagnosis.—This has to be made from Leishmanial sores and from tropical ulcer (see p. 1368).

Treatment.—Local applications of ammoniated mercury, or the nitrate of mercury ointment, often do great good. Other antiseptics may also be tried, and vaccine therapy should not be omitted. Inquiry should be made of the general condition of the health, and a tonic of iron and arsenic may be given.

PEMPHIGUS CONTAGIOSUS

Definition.—A contagious skin affection characterised by inflammatory vesicles or bullæ with ulcer formation and scabbing.

Ætiology.—This condition has lately been termed a pyosis, non-follicular in nature, and has been given the name of *Pyosis mansonii* by Castellani and Chalmers. They add a further series of pyoses, namely, *Pyosis tropica*, *P. palmaris*, *P. corletti* and *P. discoides*.

The causative agent is a staphylococcus, the *aureus* or *albus* being usually grown from the lesions. The condition more resembles an impetigo than a real pemphigus. It is common in hot, damp, steamy parts of the tropics.

Symptoms.—The lesion begins as a minute red speck, which rapidly grows larger, becoming a vesicle, then a bulla, then a bleb-like pemphigus. At first the fluid in the bleb is clear, then later becomes turbid, and generally bursts; but the process may still continue to spread. Finally, a pinkish, slightly glazed spot is left to indicate the original site of the bleb. The lesions are mostly confined to the axilla and crutch; but may be spread over other parts of the body by the fingers.

Treatment.—Cleanliness comes first. The patient should be warned against scratching himself for fear of spreading the trouble. Perchloride lotion may be used to wash the parts, followed by a dusting powder of zinc oxide, boracic acid and starch.

TROPICAL ULCER

Synonym.—Tropical Sloughing Phagedæna.

Definition.—A gangrenous condition of the skin and subcutaneous tissues, resulting in loss of tissue and the formation of sloughing ulcers.

Ætiology.—The condition is common in many parts of the tropics, especially in damp, steamy, low-lying areas. The causative agent is supposed to be a spirochæte, *Treponema schaudinni*, either alone or in conjunction with fusiform bacilli. It is specially common in the debilitated; but also may attack healthy individuals. Both sexes and all ages are liable.

Symptoms.—The sore begins as a bleb, which bursts, exposing a grey-coloured slough. The gangrene quickly spreads and involves the deeper tissues, and also extends at the point of origin. An area of some inches may be involved. Subsequently, in many instances, the sore ceases to spread and becomes limited, the sloughing tissue being thrown off. Great destruction may be caused to the deeper tissues, though in other cases the ulceration remains superficial.

Diagnosis.—This has to be made from tropical sore due to *Leishmania tropica*, and from ordinary pyogenic sores. Examination of smears will show spirochætes and fusiform bacilli.

Treatment.—Novarsenobillon injections intravenously should be tried, in view of the possible spirochætal nature of the condition. Locally powerful antiseptics (pure carbolic) or caustics must be applied, preferably under an anæsthetic. The general condition of the patient must also receive attention.

TINEA

Ringworms abound in the tropics, some being specific to those parts, while others are much the same as in temperate regions. Two may be mentioned here.

Tinea cruris (Dhobie itch).—This troublesome complaint is very common in the tropics. According to Castellani three species of *Epidermophyton* and one *Trichophyton* may give rise to the condition. The condition often excites an inflammatory eruption, which is painful and itchy, rendering the parts raw and tender.

Treatment.—If not too extensive, and not too inflamed, linimentum iodi will often cure the condition. Chrysophanic acid ointment is also used, or glacial acetic acid, or resorcin and salicylic acid. The crutch should be dusted daily with some dusting powder.

Tinea imbricata (Tokelau).—**Definition.**—A form of ringworm indigenous in certain tropical regions (chiefly the Eastern Archipelago and South Pacific), due to an *Endodermophyton*, and characterised by flaky tissue paper-like scales arranged in concentric rings.

Symptoms.—The peculiar tissue paper-like scales are very characteristic, as also the absence of inflammation. The scales are firmly attached by their bases.

Treatment.—The condition is difficult to cure. Linimentum iodi clears it away for the time being; but it is apt to return. Resorcin dissolved in tincture of benzoin (resorcin, ʒij, tinct. benzoini co., ʒi) or chrysarobin ointment 5 per cent., sometimes gives better results.

Pityriasis versicolor is also common abroad; ordinary white and black varieties are described.

PINTA

Definition.—A fungus disease associated with peculiar pigmented patches of the skin.

Ætiology.—The disease is found in parts of tropical America, is said to be contagious, and attacks both sexes and any age. A variety of fungi seem to be implicated—*Penicillium*, *Aspergillus* and *Monilia*.

Symptoms.—The patches are very striking owing to their peculiar colouring, some being blue, others red, white or black. From the parent spot others develop, till large areas of the skin are involved. The white spots do not itch or desquamate, so the possibility of leucodermia should be considered. When the scalp is affected the hair becomes white. The skin has an offensive odour.

Diagnosis.—The patches are distinguished from leprosy by the absence of anæsthesia.

Treatment.—As for ordinary ringworms.

LEUCODERMIA

There is nothing peculiar about this condition in the tropics. It is however, much more striking on a black-skinned negro than on a white skin. Occasionally an albino negro is seen.

PIEDRA

Definition.—Gritty nodosities on the hair of the scalp.

Ætiology.—The disease is seen in Colombia and South America, and is supposed to be due to a fungus. The hair appears surrounded by a sheath. The condition must not be confused with the ordinary *Trichomycosis nodosa*.

ULCERATING GRANULOMA

Synonyms.—Ulcerating Granuloma of the Pudenda; Serpiginous Ulceration of the Genitals.

Definition.—A chronic ulcerating condition of the genitals and groins, venereal in origin, and due to a short rod-shaped bacillus.

Ætiology.—The disease is very common in the Guianas in South America; it is also found in Madras, amongst the aboriginals in Northern Australia and also on the West Coast of Africa. Males and females are both subject to the disease. Children before the age of puberty do not suffer. All races suffer equally, if exposed to infection. Donovan in India first saw the parasites, but for some time there was some uncertainty as to their nature, some believing them to belong to the protozoa. Recent South American work has demonstrated they are non-motile capsulated bacteria of the rhinoscleroma group, and the name *Calymmatobacterium granulomatis* has been given to them. They occur in little round clusters in the endothelial cells of the lesions, and also in zooglœa masses in the tissues between.

Pathology.—The type of the lesion microscopically is an infective granuloma. The new-growths at the margins of the sore consist of nodules, made up of round cells in which the nuclei are difficult to see. The older parts of the lesions consist of fibrous tissue with smaller clusters of the same sort of cells. The parasites are found lying in the cells as described above. There is no suppuration or caseation in the lesions.

Symptoms.—The disease begins on the genitals as a small, slightly raised sore, which soon breaks down and leaves a small ulcerated area. The latter spreads serpiginously, the ulceration not extending deeply but gradually involving more and more of the healthy skin. It is auto-inoculable, so that apposition of adjacent parts, such as the scrotum and thighs, or the opposed surfaces of the labia, readily become affected. The whole of the groins,

the penis and scrotum in the male, and the vulva, labia and vagina in women, finally become involved, and if unchecked the ulceration eats its way into the rectum and urethra. The general health remains wonderfully good, the lymphatics not being affected, and the disease remaining strictly local. The condition, however, lasts indefinitely, partial healing occurring at some parts, while extension is taking place at others.

Diagnosis.—This has to be made from lupus, rodent ulcer, malignant disease—epithelioma—syphilis, etc. The Wassermann test is negative.

Prognosis.—This has improved with the new methods of treatment now in vogue. Formerly the condition was hopeless, lasting for the rest of the patient's life.

Treatment.—Sexual connection with infected women should be avoided. Excision of the early lesions is curative. The ulceration does not extend deeply, so the part can be cut out successfully in many instances. In past days scraping and caustics of various sorts were used. The modern treatment consists of intravenous injections of tartar emetic, which is a specific. This is given in the way described under Leishmaniasis and bilharziasis. The total dosage may have to be as high as 50 or 60 grains *in toto*. Complete cures can be effected by such treatment.

Protein shock produced by the intravenous injection of T.A.B. vaccine may also be employed in addition to the antimony. It stimulates healing in a marked manner.

G. CARMICHAEL LOW.

SECTION XIX

DISEASES OF THE NERVOUS SYSTEM

AFFECTIONS OF THE CRANIAL NERVES

INTRODUCTORY

AFFECTIONS of the cranial nerves are often very important indications, not only of local disease which may involve them at any part of their course from their nuclei of origin to their extreme peripheral distribution, but also of certain general diseases in which either the neurones are poisoned generally by toxic agents circulating in the blood or gaining access to the nervous system from local points of infection, by ascending to the nervous system along the perineural lymphatics which accompany the peripheral nerve fibres, and so delivering a local dose of poison within the nervous system, as, for example, in polyneuritis, tetanus, rabies, etc.; or the general disease may produce multiple local lesions, some of which may affect the cranial nerves, as in syphilis of the nervous system, disseminate sclerosis, tuberculosis, etc. The nuclei of the cranial nerves may be affected by local gross lesions, by toxic processes or by primary neuronie degeneration producing nuclear paralysis, which in the case of the oculo-motor and sixth nerves differs conspicuously in type from the paralysis due to lesion of the peripheral nerve trunks. Between the nuclei of origin and the point of emergence of the nerve from the surface of the brain, the nerves may be involved by inflammation, vascular lesions, tumours, syphilitic lesions and patches of disseminate sclerosis, and the resulting clinical picture will include the results of the lesion upon the other nervous structures implicated. In their sub-arachnoid course between the superficial origin from the surface of the brain and their exit through the dura mater, these nerves are apt to be involved by inflammatory conditions, such as meningitis, syphilis, tumours and pressure. During their passage through the cranial foramina, they are especially often affected by inflammatory processes involving the periosteum, as in the common Bell's paralysis of the facial nerve, and they may be injured in fracture of the skull. In their peripheral course they are prone to the same local affections as are the peripheral nerves generally. Throughout their whole course, local syphilis is by far the most frequently occurring individual lesion.

THE OLFACTORY NERVE AND TRACT

The olfactory tract gathers from two roots; an outer, which sinks into the anterior perforated region to end in the uncinate gyrus of the same side,

and an inner, which crosses in the anterior commissure to end in the uncinate gyrus of the opposite side. There is thus a semi-decussation of the olfactory path similar to the semi-decussation of the visual and of the auditory paths. From the olfactory bulb the olfactory nerves pass as many fine non-medullated nerves to be distributed to the upper meatus of the nose. The sense of smell includes the appreciation of all flavours, and in its absence taste is reduced to the appreciation of bitter, sweet, salt and sour. Only those substances are appreciated by the sense of smell, which are readily oxidisable, and for this reason this sense should be tested by means of essential oils. Most conditions of anosmia are due to affections of the nasal mucous membrane, or they follow general diseases such as influenza or syphilis, and are to be disregarded in the diagnosis of nervous disease. Unilateral anosmia is more important, and is indicative of the involvement of one olfactory tract by tumour, or pressure, and is suggestive of tumour involving the orbital lobule.

OPTIC NERVE

The optic nerve, from its origin at the back of the eyeball to its termination in the optic chiasma, is liable to injury from the pressure of tumours within the skull, or at the back of the orbit, and from inflammatory conditions of the bone and periosteum as it passes through the optic foramen. It may be affected by a primary thrombosis of vessels, or from thrombosis of the ophthalmic artery in the condition known as carotid hemiplegia. These conditions result in blindness of one eye, which may be partial or complete, and with a varying visual field, according to the degree of the lesion and the manner in which the pressure falls upon the optic nerve. On account of the cutting off of the light-reflex path, the pupil will be moderately dilated and insensitive to light. Notwithstanding the fact that the nerve cells which control the nutrition of the optic nerve fibres are situated in the retina, lesions of the optic nerve of any long duration produce atrophy of the optic disk.

RETROBULBAR NEURITIS

Inflammatory and other local lesions in the substance of the optic nerve between the globe and the chiasma are of very common occurrence. According to their severity they give rise to partial or complete blindness, which often recovers wholly or in part. The central part of the optic nerve is the seat of election for these lesions and, therefore, the visual defect appears commonly in the form of a central scotoma. According to the degree of the visual defect, the pupil tends to be dilated, and to react poorly to light, and dilate badly to shade. These conditions of retrobulbar neuritis are very often followed by optic atrophy of varying degree. When the inflammatory lesion occurs far forwards and impinges upon the optic papilla, papilloedema occurs, and, as this region is sensitive, whereas the optic nerve is not, there is usually pain in the eyeball. The prognosis in this condition varies with the causes, which are as follows:

1. *Syphilis*.—The lesion is a diffuse gumma of the nerve, and sometimes there is thrombosis. It is commonly unilateral, and often recovers, if treated early and energetically, but in severe untreated cases, and when thrombosis occurs, it not uncommonly ends in complete blindness. It is the common

cause of complete blindness confined to one eye in tabes, and in other syphilitic conditions.

2. *Disseminate sclerosis.*—Plaques in the optic nerve are very common in this disease. When they first form they are swollen oedematous pink patches and cause pressure upon the nerve fibres, and on their subsequent shrinking, this pressure is removed, and the nerve fibres recover to a great extent, and never become completely destroyed. This condition is the cause of the very common transient amblyopia or transient blindness which is met with in cases of disseminate sclerosis, and which may come on very suddenly. It may be unilateral or bilateral, and may recur many times. It always causes some degree of optic atrophy; but is never followed by complete blindness.

3. *Local septic conditions.*—Suppuration and chronic disease in the vicinity of the orbit, and particularly that of the ethmoidal cells, sphenoidal sinus, nasal cavities, frontal sinuses, antrum or even, it is said, of the teeth, are frequent causes of retrobulbar neuritis. The process presumably is an extension of organisms by the lymphatics into the optic nerve, and the setting up of a non-suppurative inflammatory process. It is more often unilateral than bilateral, but may occur first in one eye and then in the other. It usually recovers to a very considerable extent. Not infrequently the inflammation extends through the sclerotic to the papilla, and is seen on ophthalmoscopic examination as a papilloedema. This is by far the commonest cause of papilloedema confined to one eye. The diagnosis rests upon the discovery of a septic focus likely to cause the condition. The treatment is that of the cause, and, in addition, the liberal administration of mercury, and salicylates. It is unwise to operate upon the septic condition of the nose, etc., until the retrobulbar neuritis is quieted down and the vision improved by medicinal treatment, for such operation is sometimes associated with an acute and serious exacerbation of the retrobulbar inflammation.

4. *Diabetes.*—In this malady a progressive and absolutely incurable form of retrobulbar neuritis occurs. It commences with a central scotoma for colour, and the failure of vision progresses to blindness, with optic atrophy.

5. *Other toxic causes.*—Tobacco, if over indulged in, may cause a curable form of retrobulbar neuritis, commonly called "tobacco amblyopia," of which the chief sign is central scotoma, and the symptom mistiness of central vision. It recovers rapidly on the removal of the cause.

6. *Alcoholic indulgence, and especially taking of wood spirit and some other poisons,* may cause retrobulbar neuritis.

The expansion of the optic nerve within the globe of the eye is visible on ophthalmoscopic examination, and the pathological changes therein occurring afford important indications which cover the whole realm of medicine. Among these changes the most important in connection with diseases of the nervous system are: syphilitic choroiditis, as an indication of the presence of syphilis, papilloedema, which is fully described in the section on intracranial tumours, and optic atrophy.

OPTIC ATROPHY

Optic atrophy is recognised, on ophthalmoscopic examination, by a peculiar opaque whiteness and flatness of the disk, with a very high

contrast at the edge of the disk between disk and surrounding retina, both as regards colour and limitation. The lamina cribrosa—the sieve-like cross-latticing of the strands of the sclerotic through which the bundles of optic nerve fibres pass—becomes visible as a stippling of the temporal region of the disk. The vessels of the retina become atrophied, and are seen to be unduly small. In many atrophies the edge of the disk is sharply cut; but when atrophy follows papilloedema the edge is apt to be fluffy, like that of torn cotton-wool. Optic atrophy may be of three kinds—(1) Primary optic atrophy results from an original devitalisation and death of the nerve cells of the retina with their processes, which constitute the fibres of the optic nerve. This is a primary neuronie degeneration, analogous to that of the anterior horn cells in progressive muscular atrophy. (2) Secondary or retrograde optic atrophy results from lesions of the optic chiasma and optic nerve, and is the constant result of long-continued pressure upon these structures. (3) Consecutive optic atrophy follows the more severe grades of papilloedema and papillitis, in proportion as these are of long standing, and proportional to the amount of exudate, and is due to strangling of the optic nerve fibres by the oedema in the first place, and by the cicatrization subsequently. Severe degrees of papilloedema may, if pressure be relieved, recover perfectly without atrophy or impairment of sight. It may be that there is another factor in the atrophy following papilloedema, and that is the long-continued pressure of a distended infundibulum upon the optic chiasma.

Ætiology.—1. It is of frequent occurrence in familial, hereditary or congenitally installed diseases in which primary degeneration of neurones occurs, as in cerebral diplegia, amaurotic family idiocy, and hereditary cerebellar atrophy where it is characteristic of Marie's type, and sometimes occurs in Friedreich's type. It is the chief feature of the familial optic atrophies, of which Leber's type, appearing about the twentieth year, is one. It occurred in several members of a family with peroneal atrophy under our observation.

2. It is one of the common manifestations of syphilis of the nervous system, and may occur alone, but much more usually as part of the syndrome of tabes and general paralysis. It is not rarely met with in congenital syphilis. It is commonly associated with local lesions of the chiasmal region, pituitary neoplasms being the most often met with. The optic atrophy of disseminate sclerosis is not a primary optic atrophy, but is secondary to retrobulbar neuritis.

3. It may follow the exhibition of certain drugs, and noticeably the injection of the earlier used arsenic preparations, such as atoxyl, soamin and orsudan. In rare cases it has followed the use of quinine.

4. Optic atrophy has also occurred in connection with diabetes, malaria, and arterial disease, and has been probably of the nature of secondary atrophy. Its occurrence in glaucoma from increase of the ocular pressure requires no explanation.

Prognosis.—This is uniformly bad in primary atrophy. When once the degenerative process is installed, the atrophy proceeds to complete blindness, sometimes slowly, sometimes quickly, and seems entirely uninfluenced by any form of treatment, even in the syphilitic cases. We believe we have seen one permanently arrested case in a congenital syphilitic subject.

Secondary optic atrophy is frequently arrested, with the recovery or removal of the cause; but some defect of vision usually remains. Consecutive atrophy from neuritis may be of any degree of severity, from the slightest, which allows of $\frac{1}{2}$ ths vision, to the most complete with utter blindness and loss of light reflex.

OCULO-MOTOR NERVES

The third nerve has its nucleus of origin immediately below and lateral to the aqueduct of Sylvius in the mid-brain. The fibres sweep in a semi-circle through the substantia nigra and inner part of the crus cerebri to emerge on the inner side of the crus between the two diverging crura. After a short arachnoid course, it perforates the dura, and runs in the outer wall of the cavernous sinus where the relation of the several nerves from above downwards and from within outwards is the third, the fourth, the ophthalmic division of the fifth nerve and the sixth nerve, to pass through the sphenoidal fissure and supply the two internal muscles of the eye, and all the external muscles of the eyeball, except the superior oblique, which is supplied by the fourth nerve, and the external rectus, which is supplied by the sixth nerve. The branches which supply the intra-ocular muscles pass through the lenticular ganglion, which lies in the orbit close to the optic nerve. Complete paralysis of this nerve produces a dilated and inactive pupil with complete ptosis, a downward and outward strabismus and complete loss of upward, downward and inward movements. There is often no diplopia complained of by the patient, because of dropping of the lid. When diplopia is present it is a crossed diplopia, because the strabismus is divergent. There is secondary deviation of the sound eye, and false projection in the visual field.

The fourth nerve takes origin in the middle part of the general oculo-motor nucleus, and decussates with its fellow of the opposite side in the valve of Vieussens, from the lateral part of which it emerges to take a winding course round the crus, and enter the wall of the cavernous sinus. It passes into the orbit through the sphenoidal fissure, and supplies the superior oblique muscle. Paralysis produces no obvious strabismus, but in looking outwards or downwards there is a wheel movement of the globe which can be detected by observing the conjunctival vessels when the eye moves. The diplopia is most discomforting, and occurs in every position of the eyes, except on looking up. The diplopia is uncrossed, and the false image is lower than, and with its top tilted toward, the true image.

The sixth nerve has its nucleus of origin beneath the fasciculus teres in the floor of the fourth ventricle, and leaves the medulla on its ventral aspect at the junction of the medulla with the pons. It has a very long arachnoid course, and perforates the dura mater lateral to the posterior clinoid process, to gain the outer wall of the cavernous sinus, whence it runs, via the sphenoidal fissure, into the orbit to supply the external rectus muscle. Paralysis of the sixth nerve produces an internal strabismus with an uncrossed diplopia.

Within the orbit lesions of any of these nerves or of their branches may occur from perforating wounds, blows upon the eyeball or from local syphilitic lesions of a gummatous nature. Injury to the lenticular ganglion, with resulting complete internal ophthalmoplegia, not uncommonly results from

a blow on the eyeball. A lesion, confined to the nerve to the inferior oblique, occurs in rare cases from syphilis, and produces a peculiar attitude of the head, for, since the resulting diplopia occurs only above the horizontal level of the eyes, the patient constantly throws back his head, and looks down his nose to avoid the diplopia.

Lesions at the back of the orbit may involve one or more of the oculo-motor nerves, and since the first division of the fifth nerve passes through the sphenoidal fissure with these nerves, and the second division of the fifth nerve is entering the infra-orbital canal at the apex of the orbit, both these nerves are commonly involved in the same lesion. New-growths, including those of the bone, periosteal inflammation and subperiosteal hæmorrhages arising from fracture of the skull are the common lesions. There is one not infrequently occurring class of these cases, which needs special description :

OCULO-MOTOR PARALYSIS FROM ORBITAL PERIOSTITIS.—This condition is very closely allied to the common facial paralysis from exposure to cold. It may occur at any age from puberty onwards. The serum reactions for syphilis have always shown that this infection is absent. The condition may arise from exposure to cold or from septic conditions of the nose and its accessory sinuses, and sometimes without obvious cause. The malady commences with pain in the orbit, which is often severe and long lasting. Soon after some proptosis is evident, and there is tenderness on pressing the globe backwards. This is soon followed by signs of involvement of the nerves which pass through the sphenoidal fissure. The sixth nerve is the first and sometimes the only nerve involved, but usually the paralysis of this nerve is followed by that of the fourth, the first division of the fifth, the third, and the second division of the fifth nerve in that order. The final result usually is that of a total ophthalmoplegia with anæsthesia of the upper two divisions of the fifth nerve, unilateral proptosis and tenderness of the eyeball, and often excruciating and lasting pain. When the sixth nerve is involved alone, and there is no spread to the divisions of the fifth nerve, there may be little pain, and the proptosis and tenderness may be little marked. Under treatment with mercury by inunction, salicylates in full doses, warm applications to the eye and counter irritation, the condition recovers in a few weeks in the milder cases, to a few months in the more stubborn ones. Forty cases of this nature have been under our observation, and in almost all of them complete recovery has occurred. In one case, three attacks were observed, all severe; the first recovered in 6 weeks and recurred 8 years later, and recovered in 5 weeks, the third attack occurring after an interval of 17 months. In only one of these cases have we seen extension to the region of the optic foramen, and involvement of the optic nerve. Both in their mode of origin, in their commencement with local pain and tenderness, in the absence of syphilis as a cause, in the nature of the treatment which is successful in their cure, and in constancy of the recovery these cases show a marked resemblance to cases of Bell's palsy which are due to a similar periosteal lesion in the region of the stylomastoid foramen. Other of the cranial nerves may be similarly affected at their foramina of exit from the skull, notably the twelfth nerve. In one case under our care a coincident lesion of the twelfth nerve occurred, and recovered under the treatment described above.

In their course between the sphenoidal fissure and their superficial origin

from the brain stem the oculo-motor nerves may be affected singly or collectively by lesions of the outer wall of the cavernous sinus, which are usually neoplasms, or by thrombosis of the sinus. Further back they may be affected by tumours, meningitis, syphilis and by general intracranial pressure. This last factor is commonly productive of paralysis of the sixth nerves, often on both sides, from the shifting backwards of the brain stem and consequent stretching of the sixth nerves, which are at the same time exposed, during their long intrameningeal course, to the general increased intracranial pressure. It thus arises that unilateral or bilateral paralysis of the sixth nerves is of no localising significance in the diagnosis of intracranial tumours. The third nerve is sometimes similarly affected by general intracranial pressure, and this usually occurs on one side only, from lateral displacement of the brain stem as it passes through the tentorial foramen, the third nerve being pressed against the edge of the tentorium. The fourth nerve from its sinuous course seems never to be similarly affected.

Any lesion of the crus cerebri may affect the third nerve, the result being the syndrome of **Weber**—a hemiplegia of the opposite side with third nerve paralysis on the same side as the lesion.

Ætiology.—By far the commonest cause of paralysis of the oculo-motor nerve trunks, in any part of their course to their terminal branches, is syphilis, the lesion being a gummatous infiltration of the nerve. Such paralysis if diagnosed and treated early almost invariably recover. If left for long without treatment vascular changes and cicatrization in the region of the lesion may render recovery impossible. The next most common cause is intracranial tumour.

Among other causes of oculo-motor nerve trunk paralysis which have not as yet been referred to are—(1) Encephalitis, which usually produces a nuclear ophthalmoplegia, but which may cause a peripheral trunk lesion, the pathological condition productive of the latter being an inflammatory focus round the point of superficial origin of the nerve. This is most commonly met with in lethargic encephalitis; (2) disseminate sclerosis, *rarely*—though this malady frequently produces diplopia, it rarely produces a definite peripheral trunk palsy; (3) diphtheria; (4) ophthalmoplegic migraine, which may produce a severe and sometimes recurrent paralysis of one or all of the ocular nerves, and may be bilateral—this condition usually recovers if the migraine be treated; (5) it may occur in aged subjects without any obvious cause. Possibly arterial thrombosis of the nerve trunk may be responsible for this condition; (6) it may occur as a transient and as a permanent event in diabetes; (7) paralysis of the sixth nerve has been frequently noticed as a slowly transient event after the use of spinal anaesthesia.

NUCLEAR OPHTHALMOPLÉGIA.—The paralyzes just described are in terms of the anatomical distribution of the nerve trunks to the various individual ocular muscles, and must be strongly contrasted with those paralyzes due to lesions just above the oculo-motor nuclei and with those involving these nuclei. The pure supranuclear lesion separates the oculo-motor nuclei from their cerebral connections, and the resulting paralysis is in terms of conscious vision: namely, paralysis of upward movement, paralysis of downward movement, paralysis of lateral movement to right and to left respectively, and paralysis of convergence. There is no diplopia and no strabismus. Such

lesions are found just above the level of the posterior commissure. The path for lateral conjugate movements is situated lateral to the paths for upward and downward movement, and both the latter appear to cross the middle line in the posterior commissure. Unless it be a simple atrophy of the cells, the nuclear lesion must of necessity involve some of the supranuclear path fibres, some of the nerve cells, and some of the thence-emerging lower motor neurones. It involves, therefore, the movement of both eyes, but irregularly and often unequally upon the two sides. There is always diplopia, and the axes do not remain parallel. A lesion in the region of the third nucleus always causes disturbance of the functions of the pupil and of accommodation. A lesion in the region of one sixth nucleus causes complete loss of lateral conjugate movements to the same side if it involve the upper part of the nucleus, and therefore interrupts the whole of the supranuclear path for lateral conjugate movement. In the case of a lesion a little lower down, there is a major paralysis of the external rectus of the same side, combined with weakness of the opposite internal rectus; and with a lesion at the lower pole of the nucleus, the resulting paralysis exactly resembles a pure paralysis of the sixth nerve.

Nuclear ophthalmoplegia is a conspicuous feature in the following diseases: (1) All local gross lesions in the region of the oculo-motor nucleus, of which mesencephalic, pontine and pineal tumours and vascular lesions are the usual varieties. (2) Myasthenia gravis. (3) Lethargic encephalitis. (4) Polyneuritis, including diphtherial polyneuritis. (5) Veronal poisoning (the pupils are here exempt). (6) Nervous syphilis, especially in connection with tabes. (7) It occurs in rare cases as a progressive condition akin to progressive muscular atrophy.

Pathological Conditions of the Pupil and of Accommodation.—

Myosis or unusual smallness of the pupil is a common sign of syphilis of the nervous system. It is an important sign of paralysis of the cervical sympathetic. It occurs in lesions of the pons below the third nerve nucleus, is often met with in advanced age without pathological associations, and is also a symptom of the morphine habit.

Eccentricity of the pupil and varying unroundness of the pupil are important signs of nervous syphilis, and these signs occur also in lesions of the foremost part of the third nucleus.

Inequality of the pupils occurs in connection with all nuclear and peripheral ocular paralysees, and with cervical sympathetic paralysis. It accompanies all defects of vision from lesions of the visual path between the eye and the external geniculate bodies, provided the appreciation of light be unequal in the two eyes. It may be congenital or associated with inequalities of the refraction of the two eyes, and then has no pathological significance. It is commonly a sign of nervous syphilis.

The Argyll Robertson pupil or reflex iridoplegia may result from any lesion in the region of the posterior commissure, interfering with the anterior end of the third nucleus. It has been produced experimentally in animals, by severing the connection of the optic tract with the quadrigeminal region in front of the external geniculate bodies on both sides. It is an important sign of nervous syphilis, and is rarely met with except in this condition. It consists of loss of reaction to light with preservation of reaction upon convergence, and often progresses to complete iridoplegia in tabes and other conditions of nervous syphilis. A very similar condition is the inverse

combination of preservation of reaction to light with loss of reaction on convergence. The Argyll Robertson pupil occurring as a sign of gross local disease is a certain sign of a lesion in the region of the posterior commissure. Rarely it is met with in disseminate sclerosis from a lesion in this position. and it is then generally one-sided. It is not infrequent in lethargic encephalitis.

Total internal ophthalmoplegia is met with in lesions of the anterior part of the third nucleus, and in lesions of the lenticular ganglion in the orbit.

Wernicke's hemianopic pupil phenomenon is a test for the position of a lesion causing hemianopia. If the lesion is situated upon the visual path where that path contains the light reflex path, the pupil does not react when light is thrown on the blind side of the retina. In other words, this sign is present if the lesion is involving the visual path between the eye and the external geniculate body. When the lesion is between the geniculate body and the visual cortex in the occipital lobe, the pupil reacts equally well from the blind and from the seeing field.

PARALYSIS OF THE CERVICAL SYMPATHETIC

The cervical sympathetic fibres for the eye emerge from the eighth cervical and first dorsal segments of the spinal cord by white rami communicantes, which ascend via the cervical sympathetic trunk, carotid plexus, ophthalmic plexus and lenticular ganglion to the eyeball and orbit. The centre for sympathetic control is in the region of the oculo-motor nucleus, and the tecto-spinal tract connects this nucleus with the cervical region of the spinal cord. Lesions close to, but above, the level of the posterior commissure produce bilateral retraction, or "tucking" of both eyelids, while lesions of the oculo-motor nucleus at or below this level produce bilateral partial ptosis. Thus, in ophthalmoplegia from a lesion of the upper part of the third nucleus one may find either retraction or drooping of both lids, or perhaps retraction on one side, with drooping of the lid on the other side. So far as the eye and orbit are concerned, the sympathetic is the tonic retractor of the lid, the tonic protruder of the eyeball, and the tonic dilator of the pupil, and stimulation of this mechanism results in retraction of the lid or widening of the palpebral fissure, exophthalmos and wide pupil, while paralysis of the cervical sympathetic produces narrowing of the palpebral fissure (cervical sympathetic ptosis), enophthalmos and a small pupil. The excitation condition is seen in Graves' disease; the paralytic condition is of common occurrence in nervous diseases. The cervical sympathetic is also the tonic vaso-constrictor and secreto-motor nerve of the head generally, but disturbance of the mechanism does not often give rise to characteristic or important clinical phenomena. A curious lack of expression is, however, sometimes observable in the face on the side of the lesion. Cervical sympathetic paralysis occurs in the following clinical associations: (1) In all lesions of the cervical cord, especially when the last cervical and first dorsal segments or roots are damaged. It is common in syringomyelia and hæmatomyelia. (2) In lesions of the cervical sympathetic trunk by cervical ribs, trauma, pressure, growths, etc. (3) It is very common in tabes and nervous syphilis generally, where it appears as partial bilateral ptosis with enophthalmos and small pupils. It appears to be a primary neuronic degeneration in this condition and never improves.

THE FIFTH OR TRIGEMINAL NERVE

The sensory portion of the nerve impinges upon the central nervous system by sending its terminals to a column of cells which extend from as low as the third cervical segment of the spinal cord to the upper limit of the medulla, the intramedullary portion of the nerve lying outside the cell column and deep to the restiform body, and being known as the "ascending root" of the fifth nerve. In the lower part of the pons, it turns outwards and leaves the surface of the brain stem to enter Meckel's space just below the free edge of the tentorium, where it lies between two layers of the dura mater in a depression upon the superior surface of the temporal bone. Here it expands into the trilobed Gasserian ganglion, each lobe of which is continued forwards by one of the three great divisions of the nerve, which are distributed as follows:

Ophthalmic division.—The first division supplies the eyeball and lachrymal glands, the conjunctiva except that of the lower lid, the skin of the forehead and scalp up to the centre of the vertex, with the cranial bones and meninges, the mesial part of the skin of the nose, and the mucous membrane of the upper part of the nasal cavity.

Superior maxillary division.—This division supplies the skin of the upper lip and side of the nose and adjacent portion of the cheek, lower eyelid and conjunctiva and part of the temple, the upper jaw and its teeth, the nasopharynx, uvula and tonsil, and the lower part of the nasal cavity.

Inferior maxillary division.—The third division supplies the skin of the posterior aspect of the temple and adjacent parts of the pinna, the anterior and upper wall of the external auditory meatus and drum, a part of the cheek, lower lip and chin, the lower jaw, teeth and gums, the floor of the mouth, inner surface of cheek and salivary glands, and the anterior two-thirds of the tongue as far back as the circumvallate papillæ.

The greater part of the hard meninges of the brain are supplied by the fifth nerve.

The motor part of the fifth nerve takes origin from a nucleus in the grey matter of the pons, where it emerges close to the sensory root and passes through Meckel's space beneath the Gasserian ganglion to join with the third sensory division of the fifth nerve. It supplies the temporal and pterygoid muscles, the masseter, the mylohyoid, the anterior belly of the digastric, and the tensor tympani.

The chorda tympani is conveyed to the tongue by the lingual branch, which it joins on leaving the Gasserian fissure.

Symptoms of Lesions of the Fifth Nerve.—Pain over the sensory distribution of this nerve occurs from irritating lesions and reflexly, if its periphery be irritated. With organic lesions in any part of its course, the pain is followed by sensory loss, corresponding with the part involved. The peculiar disease, neuralgia, of which the pathological basis has not been as yet discovered, is practically confined to the distribution of this nerve, which cannot be too carefully learned, since pain really due to the implication of this nerve may be considered as belonging to other territories, as, for example, the pain deep in the side of the throat (tonsillar branch) and in the occipital region (meningeal branches), which are common in neuralgia. Herpes zoster over

the distribution of this nerve is common, and results from a lesion, usually a hæmorrhage or small focus of inflammation, in the Gasserian ganglion, and is in every respect comparable with that occurring in the distribution of the spinal nerves from similar lesions in the posterior root ganglia. It produces bad scarring, and when affecting the cornea is apt to produce ulceration, very destructive to the eye. It is accompanied by severe pain, which may be persistent for months. It should be borne in mind that the sensory supply to the cornea is entirely from the naso-ciliary branch, via the long ciliary nerves, and that herpes zoster of the cornea is usually accompanied by a small group of vesicles only at the tip of the nose on the same side.

Taste.—It has frequently been argued that loss of taste over the anterior two-thirds of the tongue follows destruction of the Gasserian ganglion and proximal portions of the fifth nerve. Cushing has, however, recently investigated this subject upon a series of cases of complete Gasserectomy, and has found that in every case the sense of taste was preserved. The path of taste thus seems proved. It is from the glossopharyngeal nucleus via the fasciculus solitarius, portio intermedia, facial nerve, chorda tympani and lingual nerve to the tongue.

Trophic changes.—Lesions of the first division of the fifth nerve are often productive of serious corneal deterioration and ulceration, which may be followed by septic panophthalmitis. These changes, however, have been proved to be the result of mechanical damage upon the insentient surface. If, for example, after destruction of the fifth nerve for neuralgia, the eye be carefully protected either by covering or sewing it up, these changes do not occur. After a little while, the anæsthetic cornea becomes much less vulnerable, and will stand the wear and tear of ordinary life without disturbance.

Paralysis of the motor function of the fifth nerve occurs in lesions of the nucleus in the pons, or of any part of the peripheral course of the motor division. The signs of such paralysis are not apparent to the patient, who experiences no difficulty in mastication, provided the lesion be unilateral. To the observer, the jaw deviates to the side of the paralysis on opening the mouth, on account of the action of the unopposed external pterygoid of the sound side. The masseter, as felt by the finger on its anterior edge, does not harden on biting, nor do the temporal muscles harden. The floor of the mouth does not stiffen on the paralysed side on forcibly opening the mouth.

Bilateral involvement of all the muscles supplied by the fifth nerve is the rule in all cases of progressive muscular atrophy where the bulbar nuclei are affected.

THE SEVENTH OR FACIAL NERVE

This nerve takes its origin from a nucleus in the ventral part of the reticular formation of the pons. The nerve fibres course dorsally, forming a loop round the sixth nucleus and, descending, make their exit from the brain stem at the uppermost end of the groove between the olivary and restiform bodies close to the auditory nerve, but separated from it by the pars intermedia. It passes forwards and outwards with the auditory nerve to the bottom of the internal auditory meatus where it is joined by the pars intermedia, and enters the aqueduct of Fallopius. Thence it passes outwards, and then makes a sharp turn backwards, at which angle it is enlarged to form the geniculate

ganglion. Subsequently, it runs downwards behind the tympanum, and emerges at the stylomastoid foramen to pass in the substance of the parotid gland, over the ramus of the jaw, to supply all the facial muscles of expression. Its landmark in crossing the jaw is one half-inch below the external auditory meatus, and just below Stenson's duct. In the petrous bone, it gives off a branch to supply the stapedius muscle. One quarter of an inch above the stylomastoid foramen, it gives off the chorda tympani, which enters a small foramen, the iter chordæ posterius, which leads it to the tympanum, where it crosses the long process of the malleus and enters the temporal fossa by a canal, the iter chordæ antierius, and subsequently joins the lingual, by which it is conveyed to the anterior two-thirds of the tongue and to the submaxillary and sublingual glands.

The facial is the most commonly paralysed nerve of any in the body. It may be involved in focal and general lesions of pons and medulla, as, for example, by tumours and vascular lesions, encephalitis, especially the lethargic variety, and by diphtheria, rabies, tetanus and polyneuritis. Between the medulla and the petrous bone it is prone to be the seat of origin of tumours of an especial nature, and to be pressed upon by tumours in the vicinity, and here the auditory nerve is likely to be co-involved. During its course within the petrous bone, it is often affected by caries, and sometimes by growth in the bone. At its point of exit from the stylomastoid foramen, it is very commonly affected by fibrositis, and periostitis, which give rise to Bell's palsy. In its course over the face it may be injured by the pressure of forceps at birth or by trauma in later life, and may be involved by parotid tumours.

BELL'S PARALYSIS (COMMON FACIAL PALSY)

Definition.—A very common type of peripheral paralysis of the facial nerve, of which the only known ætiological factor is exposure of the face to cold, and accompanied in a great majority of the cases by signs of local fibrositic inflammation in the region of the stylomastoid foramen. The paralysis almost invariably recovers, but if the recovery is slow, a very peculiar spasm or facial contracture accompanies or follows the recovery. This contracture in its turn disappears slowly.

Ætiology.—Facial paralysis is very rare at the extremes of age and it is most common in early adult life. The sexes are equally affected. The only definite known cause is local exposure of one side of the face to cold, such as driving in a wind or sitting in a draught. Many different views have been held as to the pathogenesis of Bell's palsy, but it seems certain that it is the result of a local inflammation of the fibrous tissue forming the deep part of the sheath of the parotid gland, from which a process in the form of a sheath accompanies the facial nerve into the Fallopian aqueduct and along which the inflammation extends and compresses the facial nerve in that canal. The proofs of this view are, that facial paralysis is so often accompanied at its onset by pain in the stylomastoid region and behind the mastoid process and by tenderness on pressure, and that in some cases there is very considerable swelling of the deep part of the parotid gland. In several cases this swelling has been so great as to cause me to admit the patients into hospital with a diagnosis of growth of the stylomastoid region, where the subsequent course of the cases proved them to be cases of Bell's paralysis of a simple

type. Moreover, it is obvious that the pathological process begins outside, and subsequently spreads up the facial canal, since the loss of taste in the anterior two-thirds of the tongue, from involvement of the chorda tympani, is so often not present when the palsy first appears, and develops in the course of a few days, as the inflammatory process spreads up the facial canal, and reaches the region where the chorda tympani leaves the facial trunk.

Symptoms.—The onset is usually rapid and sometimes even sudden. It may follow definite exposure of the face to cold, but often there is no such history. Pain of a neuralgic character below the ear, behind the mastoid process, or referred to the occipital region, is common, but it does not last more than a few days, and sometimes pain is entirely absent. On deep pressure upon the styloid region behind the ramus of the jaw on both sides, one can almost always elicit the fact that there is tenderness on the paralysed side, and sometimes obvious swelling of this region may be felt. The first sign of the facial paralysis is that the patient feels the face to be stiff when he attempts to move it. Subsequently, the paralysis appears rapidly, and the face is drawn over to the opposite side. The paralysed side is motionless, according to the degree and distribution of the paralysis, if incomplete, and, if complete, is expressionless. The eye cannot be closed, and there is epiphora from paralysis of the tensor tarsi. The paralysis at the corner of the mouth causes difficulty in articulation and escape of fluids on drinking, but the patient soon learns to dodge these disabilities. When the paralysis is partial it is nearly always the lower part of the face which is the most affected. The facial muscles soon become hyperexcitable to mechanical stimuli, and in complete cases present a reaction of degeneration in a few days. In nearly all the severe cases, there is loss of taste over the anterior part of the tongue. It should be remembered that the sense of taste is confined to a very small area on the lateral edge of the tongue, some half an inch behind the tip.

There is never any pain in the distribution of the facial nerve. After a time, which may vary from a few days to two years, the paralysis begins to recover, and almost invariably this recovery appears in the upper facial region first, and in almost every case becomes complete. We have seen perfect recovery follow complete paralysis lasting 21 months.

Diagnosis.—Great care in diagnosis is necessary lest peripheral facial palsy of very unfavourable prognosis should be mistaken for it. The facial palsies which result from lesions of the nerve in the temporal bone, from caries and from tumour, those due to lesion of the nerve within the skull and from pontine lesions, rarely make any recovery. To this rule the following exceptions must be made: In the peripheral facial paralysis of poliomyelitis, lethargic encephalitis, tetanus and diphtheria recovery always occurs, if the patient survives.

Facial contracture.—In cases of long duration when recovery commences, the face goes into a condition of persistent spasm which causes often a very unsightly distortion of the face, which is very disappointing to the patient, who after waiting many months for improvement, now finds the face distorted in the opposite direction and to a more severe degree than at the onset. No adequate explanation of facial after-contraction has ever been put forward, and no similar condition occurs after the lesion of any other peripheral motor nerve, so far as we are aware. It recovers slowly in the

majority of cases. Patients should be warned from the first about the occurrence of after-contracture so that disappointment may be obviated, and at the same time encouraged as to the probability of complete recovery.

The diagnosis is not difficult, and mistaken diagnosis means faulty examination. In disease of the temporal bone, the facial palsy is accompanied by signs of such disease, which should be carefully sought, namely, deafness, perforation of the drum, discharge from the ear, and signs of long-standing otitis.

Lesions within the skull are apt to co-involve the auditory nerve, the fifth nerve or the cerebellum, and the characteristic signs of tumour of the lateral recess are common. In the pons, hemiplegia, hemiataxy and hemi-anæsthesia are likely to coexist.

Course and Prognosis.—Recovery is so usual that it should be promised in every case. The date of recovery is often difficult to forecast. If at the end of a week after the onset there is the slightest trace of any voluntary power in the orbicularis palpebrarum, which is the "ultimum moriens" of the facial muscles, or if any trace of faradic excitability to bearable stimuli remains, then it may be confidently said that recovery will be complete and rapid within 3 months, and that there will be no contracture. Cases in which no complete paralysis occurs in any region of the face usually recover in a fortnight. In complete cases, with complete reaction of degeneration in the muscles, it is difficult to say when recovery will occur or when the effect of contracture will be at an end. Cases which show no loss of taste and, therefore, in which there is no great extension of the inflammatory process up the facial canal, usually recover rapidly. Traumatic facial paralysis from blows upon the side of the face, and obstetrical facial paralysis from the pressure of forceps during delivery, always recover and leave no sequelæ.

Treatment.—The immediate treatment at the onset should be that suitable for the amelioration of a fibrositic inflammation. Mercury by inunction and salicylates and iodides internally are most valuable. While there is pain, the application of warmth or the use of counter-irritants, of which the best is strong tincture of iodine, is indicated. Massage to the face should be used from the onset. It is really doubtful whether electricity in any form or at any time materially helps in recovery, but in the present day any failure will be assuredly attributed to its non-employment, and therefore galvanism may be used. Electricity should never be used where there is after-contracture, for it increases this condition.

Facial paralysis from caries of the temporal bone rarely makes any recovery, and it is almost always complete and permanent. To remedy the unsightly and permanent distortion of the face, union of the peripheral trunk of the facial to the central end of the divided spinal accessory or preferably the hypoglossal nerve, has been performed, and with considerable success. Section of the hypoglossal with consequent hemiatrophy and hemiparalysis of the tongue produces no disability with speech, mastication or swallowing. It is not so much that re-union of this nerve restores volitional power to the face, but associated movement does return and also some after-contracture, which restores to some degree the symmetry of the face.

PERIPHERAL FACIAL SPASM

Definition.—A unilateral malady of the facial nerve, in which intermittent spasm of the facial muscles occurs, exactly like that caused by faradism of the facial trunk. It is occasionally associated with a slowly oncoming facial paralysis, and may follow a facial paralysis due to injury.

Ætiology.—This malady occurs in adults, and the onset is usually insidious and without known cause. We have seen many cases, however, during the Great War in which injuries in the region of the facial nerve in its course through the temporal bone, such as gunshot wounds, shell fragment wounds with much scarring, and contusions with much bruising of this region, have been followed by peripheral facial spasm. It is certainly due to a lesion of the peripheral facial nerve trunk, and this lesion seems to be of such a nature as to irritate, and not in most cases to destroy; but in some cases partial destruction, with the appearance of partial facial paralysis, does occur.

Symptoms.—It commences with twitching of some part of the facial musculature, which occurs at first at rare intervals, and subsequently becomes more and more frequent, so as in some cases to be almost continuous. Commencing locally, it tends to spread so as to involve the whole face in a sudden and hideous contortion. We have seen cases in which the attacks of peripheral facial spasm at first glance almost exactly resembled a Jacksonian fit of the face, the obvious distinction being that no Jacksonian fit can be confined to the supply of the facial nerve, but eyes, tongue, etc., are also involved. The spasms may be so severe and continuous as to keep the eye closed for long periods together, and to interfere greatly with the work and enjoyment of life. The malady is associated with no other symptoms. Cases exist in all degrees of severity, from the mildest, in which an occasional flicker of the face occurs, to the most severe and incapacitating and unsightly malady.

Course and Prognosis.—Some of the cases recover spontaneously, and others under treatment; but when the malady becomes severe and the spasm hardly remitting, it is practically intractable, except by operative interference.

Treatment.—In the milder cases, measures calculated to subdue chronic inflammation, such as mercury, iodides and salicylates, are sometimes of remarkable benefit. In severe cases, the only remedy which affords relief is the injection of alcohol into the facial nerve either at the stylomastoid foramen, or as it crosses the ramus of the jaw half an inch below the external auditory meatus, or when one division of the nerve only is affected, in any part of the pes anserinus. Brilliant results have followed this method, which was first used by Patrick. A facial paralysis has been produced which quickly passes off with complete relief of the spasm, sometimes permanently, sometimes temporarily, but always for such a time as to make this slight operation a brilliant success. Weak alcohol should be used so as to damp down rather than destroy the facial fibres, 40 per cent. to 60 per cent. The needle must be introduced with great accuracy and the injection made very slowly, not more than a minim at a time, the face being watched all the time, while the patient is repeatedly instructed to move it. With the first sign of oncoming weakness the injection is stopped, for this weakness will deepen considerably from diffusion effect after the injection.

Herpes from lesion of the geniculate ganglion.—Under this title an affection

has been described by Ramsay Hunt in which herpes zoster in and about the external auditory meatus has occurred, and in some of the cases this has been complicated with facial palsy, and occasionally with symptoms indicating irritation of the auditory nerve. Such cases are by no means rare. The inconspicuous herpetic vesicles situated in the concavity of the concha should be looked for in every case of Bell's palsy.

THE AUDITORY AND VESTIBULAR NERVES

The auditory or cochlear nerve takes origin from the spiral ganglion of the cochlea, situated near the inner edge of the osseous spiral lamina. The cells of this ganglion are bipolar, and their peripheral processes are distributed to the organ of Corti while the central processes pass down the modiolus of the cochlea and through the internal auditory meatus, where they join those of the vestibular nerve, to the upper part of the groove between the restiform and olivary bodies, where they end among the cells of the tuberculum acusticum and cells of the ventral nucleus. This nerve is concerned entirely with the sense of hearing.

The vestibular nerve takes its origin in the cells of the ganglion of Scarpa, which is situated at the outer end of the internal auditory meatus. The peripheral processes supply the labyrinth and semicircular canals; the central processes join with those of the cochlear nerve and course to the upper end of the groove between the olivary and restiform body. Here the vestibular fibres diverge from the cochlear fibres, and passing between the restiform body and the ascending root of the fifth nerve, end in a mass of nerve cells called the vestibular nucleus, beneath the lateral part of the floor of the fourth ventricle.

The central path for the impressions conveyed by both the cochlear and the vestibular nerves is believed to undergo a semi-decussation similar to that of the olfactory tracts and optic nerves.

Lesions of the cochlear nerve produce deafness, and in addition pathological changes in its peripheral termination are productive of tinnitus. Except from direct involvement of this nerve or of its terminations in the cochlea, deafness is practically unknown as a symptom of disease of the nervous system. In other words, lesions of the central auditory paths are not as yet recognisable by any known symptoms.

Nerve deafness may be produced by any lesions of the cochlea and cochlear nerve, and is confined to diseases of the temporal bone and labyrinth, lesions of the intermeningeal part of the eighth nerve by tumours, meningitis or pressure, and lesions of the lateral side of the medulla. The deafness is the same wherever the lesion may be, and the position of the lesion is to be deduced from the associated involvement of contiguous structures. Nerve deafness, which characterises lesions of the cochlea and its nerve, is distinguished from deafness due to middle-ear disease by the facts that hearing both by air conduction and by bone conduction is diminished or lost, while in middle-ear deafness the hearing by bone conduction is increased. If a tuning-fork in vibration be applied to the forehead until it is no longer audible, and then presented to the ear, it will not be heard aurally in middle-ear disease, since the aerial conduction is impaired in that condition. But in nerve deafness it is either not heard through the bone when the tuning-fork

is applied, or if heard, when it has ceased to be audible to bone conduction, will still be audible when presented to the ear. This is known as Rinne's test, and it is a reliable one. Weber's test for nerve deafness consists in the application of a tuning-fork to the forehead in the middle line, the patient being asked which ear the sound comes to most. In middle-ear deafness the sound is heard best on the deaf side, and in nerve deafness it is best heard on the sound side. As a symptom of nervous disease, nerve deafness is met with in disease of the lateral region of the medulla, in tumours of the cerebello-pontal angle growing from the eighth nerve, following epidemic meningitis, and in syphilis of the nervous system, especially congenital syphilis.

TINNITUS

Ætiology.—Tinnitus or the occurrence of persistent recurring noise referred to the ears may be produced by wax in the ear, by otitis media, or by any other condition of vascular congestion, or by inflammation in the region of the auditory mechanism. It occurs in those who work exposed to deafening noise, as in boiler-makers and riveters, and may be produced by the administration of quinine and salicylates. It is much more frequently indicative of a mysterious and intractable disease of the cochlea, which often ends in complete deafness. Persistent tinnitus is a malady of adult life, the earliest cases occurring after puberty. It is rare for the malady to commence in old age. It begins insidiously, and as a rule without cause, but debilitating influences may precede its onset.

Diagnosis.—The diagnosis of tinnitus presents no difficulty. A careful examination of the ears will discover and cause to be removed any local trouble in the external auditory meatus and tympanum. Moreover, these conditions do not give rise to persistent tinnitus with nerve deafness.

Symptoms and Course.—The sounds commence faintly and often intermittently, and at first may be only perceived in stillness and silence at night, and later become louder and more persistent, and are often absolutely continuous. The slight sounds may be low pitched, a low rumble like a distant wagon, or a faint murmur such as may be heard when a shell is held to the ear. The loud sounds are never low in tone. They may be humming, hissing, rushing or bell-like noises. The common simile used by the patient is that of a hissing kettle, of a gas jet, of a threshing machine, of a steam-engine, or of a room full of machinery. The same patient may have several sounds, sometimes successive and sometimes heard all at once. When the sounds are rhythmic they are usually synchronous with the pulse. In some of the cases labyrinthine vertigo occurs, and the attack may be heralded by an increasing intensity of the sound. The condition of hearing in patients suffering with tinnitus may vary in each case, and from time to time in any one case. In many cases hearing is perfectly normal, and may remain so for years, in spite of increasing tinnitus. One of my patients retained perfect hearing for over twenty years, with increasing tinnitus; but the hearing rapidly declined afterwards. In many cases, however, there is some degree of nerve deafness on one or both sides. In the course of time the deafness increases even to absolute deafness, and in a few of them the noises persist in spite of absolute deafness. As a rule, the noises decrease as deafness becomes severe.

Prognosis.—The prognosis is very uncertain, and for the most unfavourable. In many cases the noises persist in spite of all treatment, sometimes treatment secures considerable relief, and not infrequently the symptom is removed by treatment.

Treatment.—In the early stages the disease may be much benefited by the exhibition of salicylates and iodides. As a symptom, tinnitus is more affected by bromides than by any other drug, and these should be given in doses of from 10 to 20 grains twice or three times daily. The effect of the bromide is sometimes increased by the addition of from 5 to 10 minims of tincture of belladonna. Frazier has reported a successful intracranial division of the auditory nerve in a case of tinnitus. Such a procedure could be only admissible where the trouble was confined to one side. This operation has proved immediately fatal in one case.

VERTIGO

Definition.—The word “vertigo,” which by derivation means a “turning,” is used to designate any movement or sense of movement or unsteadiness either in the individual himself (subjective vertigo) or in external objects (objective vertigo) that involves a defect, real or seeming, in the equilibrium of the body. It is a sensation of involuntary movement, either of subject or of external objects. It always involves a slight interference with consciousness, and in severe vertigo consciousness is often momentarily lost.

Ætiology.—Vertigo is always the result, direct or indirect, of disturbance of the labyrinth, vestibular nerves or cerebellum. It is commonly associated with vomiting and with vasomotor and secretory phenomena, such as “cold perspiration.” The disturbance of the vestibular mechanism which results in vertigo may be set up by multitudinous causes, among which may be mentioned toxic states as in specific fevers, and from the administration of alcohol, anæsthetics and morphine, irregularities of blood supply as in fainting, loss of blood, cardiac feebleness, Stokes-Adams’ disease, and sudden alterations of position and in arterial disease; from visual or bodily disorientation as in diplopia, dancing, swinging, sea-sickness and train-sickness; in anæmic states; in migraine, and as an aura in epilepsy; in diseases of the tympanum, labyrinth and semicircular canals; in diseases of the vestibular nerve and cerebellum, and in conditions of raised general intracranial pressure.

Diagnosis.—The vestibular mechanism is closely connected functionally with the cerebellum, and the symptoms which result from its disturbance are almost identical with those resulting from lesions of the lateral lobe of the cerebellum, and comprise nystagmus to the side of the lesion, vertigo, forced movements, hemiataxy and hypotonus on the side of the lesion. There are two points which serve to separate the two conditions. In the first place, vestibular lesions are usually associated with nerve deafness, which is absent in cerebellar lesions, and secondly, the cerebellar symptoms are only marked in vestibular lesions when the condition is acute, or during acute exacerbations.

Tests for vestibular lesions.—1. Barany’s caloric test is made by irrigating the external auditory meatus with either hot or cold water or air. With an intact vestibular mechanism this causes irritation of the vestibular appa-

tus with the appearance of nystagmus or lateral deviation of the eyes to the side of the irrigation. When the vestibular mechanism is impaired this test fails relatively or completely.

2. If the patient be rotated either by placing him in a special rotating chair, or by turning him round several times in the standing position, lateral conjugate deviation of the eyes immediately after the rotation will show nystagmus in the opposite direction to the rotation, if the labyrinth on that side is intact. It will not appear if the functional activity of the vestibular mechanism is deficient.

MÉNIÈRE'S DISEASE (LABYRINTHINE VERTIGO)

Definition.—A malady in which paroxysmal attacks of severe labyrinthine vertigo occur at irregular intervals, associated with tinnitus and progressive deafness, and due to disease of the labyrinth of a chronic nature.

Ætiology.—Little is known of the causal factors in this disease. It is a disease of adult life, and usually appears without definite antecedents. Ménière, who described the clinical picture of the malady, considered that hæmorrhage into the labyrinth was responsible for the condition; but in view of the frequency with which the attacks may occur, and the very slow loss of vestibular function which accompanies the course of the disease, it seems highly improbable that so destructive a lesion as hæmorrhage can be responsible for the majority of the cases.

Symptoms.—The attacks set in suddenly with a buzzing noise in the ears, followed immediately with intense vertigo, both subjective and objective. The vertigo may be so intense that the patient feels he is hurled to the ground. He often falls as if shot; sometimes he has time to assume the sitting or lying position, before the vertigo reaches its height. Consciousness is often lost, or seriously impaired, for a few moments only. Spontaneous nystagmus occurs to the side of the lesion, and unilateral cerebellar signs on the side of the lesion. The patient becomes nauseated, and often vomits repeatedly. The skin is pale and covered with a clammy sweat. The patient lies perfectly still, and in terror lest the least movement should bring on more vertigo. The duration of the attack and the time taken in the recovery from an attack vary from a few minutes to 24 hours. Sometimes the attacks are excited by some sudden movement, such as coughing or sneezing, but they are usually without any such antecedent. They may occur during sleep, and wake the patient. The recovery from the attack is usually perfect, the vertigo disappearing; but in some cases slight persistent vertigo remains between the attacks. When Ménière's disease is persistent a slow onset of nerve deafness and signs of slow vestibular destruction follow, and as these signs deepen the attacks become less and less severe, and finally cease when the functions of the labyrinth become destroyed.

The diagnosis of Ménière's disease presents no peculiar difficulty, for the symptoms are highly characteristic, and although the attacks vary in the degree of their severity, from a slight momentary giddiness to a sudden falling, with the most acute cerebellar symptoms, yet the first attack is usually severe. The rapid disappearance of the symptoms is striking. Vertiginous attacks from all other causes must be excluded. In epilepsy consciousness

is usually lost. In Ménière's disease it is momentarily impaired, and there is no convulsion. In acute cerebellar lesions the symptoms are very like those of labyrinthine vertigo, but they are not transitory in a few hours. A careful search of the nervous system for signs of organic nervous disease should in every case avoid any mistake.

Prognosis.—The outlook in Ménière's disease is uncertain. Some cases go from bad to worse in spite of treatment, and progressive deafness ensues with disappearance of the attacks. Many cases however recover perfectly with little or no impairment of hearing.

Treatment.—The salicylates seem to have a definite specific effect upon the morbid process, and should be given in doses of 20 grains thrice daily. In the form of aspirin they may be even more beneficial from the sedative effect of the latter drug. The bromides have a wonderful effect in relieving the symptoms, and in averting the attacks, to the extent that it may be said that labyrinthine vertigo may be almost diagnosed by the beneficial effect of bromides upon it. They should be given in doses of from 10 to 20 grains three times a day. Syphilis must be excluded, and if present, treated. Counter-irritation of the mastoid region has been recommended, and can certainly do no harm.

ACUTE VESTIBULITIS

In this rare disease slight general febrile symptoms are followed rapidly by severe bilateral cerebellar symptoms, intense vertigo, incessant vomiting and bilateral ataxy, which entirely prostrate the patient. The symptoms begin to remit in the course of 2 or 3 days, leaving complete bilateral and permanent deafness. The cerebellar or vestibular symptoms clear up in the course of a few weeks. This condition seems to be dependent upon an acute inflammatory condition of the labyrinth and cochlea. Four cases have been under my personal observation. The malady at first resembles an acute bilateral lesion of the cerebellum; but the rapidly increasing deafness, which soon becomes absolute, should serve to distinguish the conditions. Jenkins has suggested an early tapping of the semicircular canals to avoid the deafness, which he considers due to the increase of perilymph pressure.

ENDEMIC PAROXYSMAL PARALYSING VERTIGO (GERLIER'S DISEASE)

Gerlier in 1887 described a curious endemic disease, occurring only in a certain district of the canton of Geneva, with which cowherds and workers in the fields alone were affected, and only in the summer months. Miura has reported a similar endemic condition in the northern regions of Japan. A typical attack may be described as follows: the patient, usually a vigorous young man, is suddenly seized with pain in the neck and back and with vertigo, and the sight becomes clouded to the point of temporary blindness. Bilateral ptosis occurs, and all the bodily muscles become weak; the patient reels, and has all the appearance of drunkenness, and often falls. After a period, not exceeding 10 minutes, rapid recovery takes place. This malady has never been known to be fatal.

THE NINTH OR GLOSSOPHARYNGEAL NERVE

This is a mixed nerve, which takes its origin by 5 or 6 filaments, from the upper end of the groove between the olivary and restiform bodies, continuing the line of the vagus roots, of which it is in reality a part. The motor fibres take origin from cells immediately below those of the facial, and above those of the ventral motor nucleus of the vagus, and are conveyed in the trunk of the nerve for the supply of the stylo-pharyngeus and middle constrictor of the pharynx.

The sensory fibres arise in the two ganglia, jugular and petrous, which lie in the jugular foramen on the trunk of the nerve, which here is placed in a special compartment of its own outside that containing the vagus and spinal accessory nerves, and between the inferior petrosal sinus in front and the lateral sinus behind.

The sensory branches enter the fasciculus solitarius, and end in the neighbouring grey matter.

The mixed nerve trunk appears in the neck between the jugular vein and the internal carotid artery. Coursing downward beneath the styloid process and over the carotid artery, it turns forwards over the stylo-pharyngeus and beneath the hyoglossus, to end in the posterior third of the tongue. Lesions of this nerve involve loss of taste over the posterior one-third of the tongue, with some unilateral paresis of the pharynx. It is rarely involved alone; but, with the other nerves taking origin in the neighbourhood, by tumours of the lateral region of the medulla.

THE TENTH OR VAGUS NERVE

This nerve is a mixed nerve. The motor fibres arise from two long columns of cells in the medulla, a dorsal column of small cells and a ventral column of large cells, called the nucleus ambiguus. They supply the voluntary muscles of the soft palate (except the tensor palati), pharynx and larynx in conjunction with the accessory fibres, and the non-striped muscles of the respiratory and alimentary tracts.

The sensory fibres take their origin from the ganglion of the root which is situated in the jugular foramen, and from the ganglion of the trunk which is situated just below the skull. Their central connections are with the fasciculus solitarius and surrounding nerve cells.

The vagus nerve takes its superficial origin from the medulla in the groove between the olivary and restiform bodies in the line of the glossopharyngeal and accessory roots. It leaves the skull along with the accessory nerve by the inner division of the jugular foramen, and appears in the neck between the jugular vein and internal carotid artery, and enters the carotid sheath. On the right side the nerve enters the thorax by crossing the first part of the subclavian artery, behind which its recurrent laryngeal branch passes upwards, and behind the innominate vein. It reaches the side of the trachea, forms the posterior pulmonary plexus on the back of the root of the lung, and subsequently the plexus gulæ on the œsophagus, and enters the abdomen through the œsophageal opening, and is distributed to the posterior surface of the stomach and cœliac plexus. On the left side the nerve enters the thorax between the left carotid and subclavian arteries and behind the

innominate vein, and crosses the arch of the aorta, behind which its recurrent branch ascends, and subsequently follows a course similar to that on the right side. Just below the ganglion of the trunk the vagus is joined by the bulbar fibres of the accessory nerve.

The sensory fibres of the vagus supply the respiratory tract, the pharynx and œsophagus. Its visceral fibres supply the lungs, heart and abdominal viscera. No sensibility seems to be supplied to the abdominal viscera by this nerve, since with division of the spinal cord above the offshoot of the splanchnic nerves all sensibility in the abdomen is lost.

LESIONS OF THE VAGUS.—The important signs of lesion of this nerve and its nuclei are pharyngeal and laryngeal paralysis and loss of sensibility. Symptoms indicative of lesions of its complicated and mysterious visceral supply are neither well marked nor well understood, and in unilateral lesions seem to be entirely absent; they are therefore not considered.

Lesions of the vagus in the medulla are common. Syringomyelia, when affecting that region, usually involves the nucleus ambiguus, causing unilateral palsy of palate, pharynx and larynx. Thrombosis of the posterior inferior cerebellar artery which supplies that region of the medulla containing the nucleus ambiguus is likely to produce vagus paralysis of the same side. Progressive muscular atrophy, in the form of progressive bulbar paralysis, may affect its cells, as does often polyneuritis and lethargic encephalitis and rabies. Lesions of the nerve roots often occur from tumours of the lateral region of the medulla, and growths outside the medulla from nerve roots and meninges, and here the lesion of the vagus roots is associated usually with those of the glossopharyngeal, spinal accessory and hypoglossal. In the neck perforating wounds and growths may implicate the nerve, and in the thorax tumours, particularly aneurysms and new-growths, are apt to cause paralysis of the muscles supplied by its recurrent branches.

Unilateral pharyngeal paralysis.—This is characteristic of all unilateral lesions of the vagus high up. It is recognised by the low-lying motionless palate and the loss of sensibility of one side of the pharynx, with loss of the pharyngeal reflex on that side. There is no impairment whatever of deglutition.

Bilateral pharyngeal paralysis.—This results from nuclear lesions of the nucleus ambiguus on either side, and is common in diphtheria, polyneuritis, myasthenia gravis and progressive muscular atrophy. The whole palate is low and paretic or paralysed, the voice is nasal, there is nasal regurgitation of liquids, the cheeks cannot be forcibly blown out, and there is difficulty in pronouncing final “b” and “g,” the words “rub” and “egg” becoming “rum” and “enek.”

Total unilateral laryngeal paralysis.—Since the superior laryngeal nerve which supplies the cricothyroid muscle, which is the chief tensor and adductor of the vocal cords, is given off high in the neck from the ganglion of the trunk of the vagus, it follows that total paralysis of the larynx on one side can only result from a lesion of the vagus, between the ganglion of the trunk and the nucleus ambiguus in the medulla. The vocal cord on the paralysed side is motionless in the cadaveric position—that is, midway between abduction and adduction. The larynx is insensitive on the same side. There is some loss of tone of voice but no stridor.

Unilateral abductor paralysis or recurrent laryngeal paralysis.—This occurs

from all lesions of the trunk of the vagus below the ganglion of the trunk, and from lesions of the recurrent laryngeal branch. The vocal cord on the side of paralysis lies close to the mid-line. It fails to abduct on taking a deep breath. There is no change of voice; but there may be slight stridor on inspiration—the sensibility of the larynx is not affected.

Bilateral abductor paralysis.—This condition is most commonly seen in the earlier stages of nuclear laryngoplegia, and is most often met with in tubercles, sometimes in bulbar paralysis, and we have seen it in disseminate sclerosis. It occurs also in bilateral lesions of the recurrent laryngeal nerves in the thorax, which may occur from aneurysm and new-growths. It is the most dangerous form of laryngeal palsy, as the vocal cords cannot be abducted from close to the middle line, and they tend to open during expiration, but to suck together during inspiration, and for this reason may cause death from asphyxia, or necessitate laryngotomy.

THE ELEVENTH OR SPINAL ACCESSORY NERVE

This is a purely motor nerve consisting of two parts, a spinal portion and a bulbar portion. They arise from the ventro-lateral cells of the anterior horn from the level of the fifth cervical segment to that of the lower third of the olive. The lower spinal fibres leave the cord in the middle of the lateral column, while above they are blended with the posterior roots, and go to supply the sternomastoid and trapezius muscles. The bulbar fibres join the vagus nerve below the ganglion of the trunk. On emerging from the spinal cord the spinal fibres ascend between the ligamenta denticulata and the posterior roots, and turning outwards at the level of the olive pass through the jugular foramen in the same compartment as the vagus nerve, and appear in the neck between the jugular vein and internal carotid artery. The nerve crosses the jugular vein, and enters the anterior border of the sternomastoid muscle an inch below the mastoid process, and leaves this muscle at the middle of its posterior border to cross the posterior triangle of the neck and end in the trapezius muscle. This nerve may be caught with the vagus by lateral lesions outside the medulla, or by lesions in the region of the jugular foramen; but it is more often damaged by injuries to the neck, and by operations for the removal of cervical glands. The spinal accessory nerve, as it crosses the posterior triangle of the neck, is very liable to injury, either from blows or from sudden strains, and most of the isolated trapezius palsies are due to local neuritis of the nerve trunk, so arising. Paralysis and wasting of the sternomastoids is conspicuous in most cases of myotonia atrophica. That of the trapezius is often conspicuous in the facio-scapulo-humeral type of myopathy. Both muscles are commonly affected in progressive muscular atrophy.

When the sternomastoid is paralysed there is neither weakness complained of, nor deformity, nor peculiar attitude of the neck, other muscles compensating for its paralysis. The muscle does not harden when turning the head to the side opposite the paralysis, and its reaction to faradism is diminished or lost.

Paralysis of the trapezius, on the other hand, causes great disability in raising the arm above the horizontal level of the shoulder and also difficulty in shrugging the shoulder or approximating the scapula to the middle line

behind and therefore also in carrying the extended arm backwards. It produces a very ugly deformity, for the scapula unsupported by the trapezius rotates so that the superior internal angle appears as a hump in the slope of the neck above the clavicle, and there is also winging of the angle of the scapula with the axillary border of that bone horizontal. This paralysis of the trapezius may be confused with that of the serratus magnus, for in both winging of the angle of the scapula is marked. In trapezius palsy, however, the deformity is much more marked, the scapula is farther away from the spine, and is much more rotated. Tests for the movements of these two muscles and the faradic excitability should prevent any confusion.

THE TWELFTH OR HYPOGLOSSAL NERVE

This is a purely motor nerve, which takes origin in a column of large nerve cells in the lower part of the medulla. The filaments leave the medulla in the groove between the pyramid and olivary body and pass through the anterior condylar foramen, whence the trunk of the nerve inclines forward, between the jugular vein and the internal carotid artery to the lower border of the digastric muscle and is thence directed forwards above the hyoid bone and resting upon the hyoglossus muscle, to the under part of the tongue. Below the skull the hypoglossal nerve has an important connection with the first and second cervical nerves, from which the nerve supply to the descending muscles from the hyoid bone is derived. The hypoglossal nerve supplies all the muscles of the tongue, both intrinsic and extrinsic.

Unilateral lesions of the hypoglossal nerve are usually the result of tumours in the lateral region of the medulla, or local lesions just lateral to the medulla, and catching the nerve roots. At the anterior condylar foramen the hypoglossal nerve is sometimes the seat of an acute fibrositis, which gives rise to a hypoglossal palsy associated with pain, and recovering in every way comparable to Bell's palsy of the facial nerve. Syphilis is a not uncommon cause of hemiatrophy of the tongue, the lesion being a gumma on the hypoglossal nerve. Hemiatrophy of the tongue is perhaps more commonly seen in tabes than in any other condition. A hemiatrophy also occurs in cases of facial hemiatrophy, where the lower distribution of the fifth nerve is the region affected; but this variety does not involve paralysis of the tongue. Spastic paralysis of the tongue, with well-marked dysarthria and dysphagia, occurs in double hemiplegia and amyotrophic lateral sclerosis. Atrophic paralysis of the whole tongue, with exactly similar defects of articulation and swallowing, occurs when the hypoglossal nuclei are affected, and is commonly seen in progressive bulbar paralysis and sometimes in polyneuritis and myasthenia gravis. The sole physical sign of a lesion of one hypoglossal nerve is atrophic paralysis of one side of the tongue with loss of faradic excitability. The affected side of the tongue shrinks and comes in the end to consist solely of mucous membrane, fibrous tissue and glands. The tongue becomes sickle-shaped, with the concavity on the paralysed side. There is little impairment of movement, and no defect of articulation from a unilateral lesion.

The treatment is that of the condition causing the paralysis.

TRIGEMINAL NEURALGIA

Synonym.—Tic Douloureux.

Definition.—A disease of the fifth cranial nerve, in which no definite morbid changes in the nerve have been discovered and in which no loss of function, either motor or sensory, occurs in the distribution of the nerve. The chief feature of the malady is the occurrence of pain of varied intensity which tends to be paroxysmal, and is often excruciating. Tenderness over the branches of the fifth nerve is always present during the bouts of pain, and when the third division of the trigeminal nerve is affected there is conspicuous unilateral furring of the tongue when pain is present.

Ætiology.—The malady is first met with at the age of puberty; it is not seen in childhood. In the earlier years of adult life it is often a mild and curable condition, though notable exception to this rule may occur; but as age advances, and especially after the age of 50 years, it tends to be increasingly severe and intractable by any measures save those for the destruction of the affected branch of the nerve, or of the Gasserian ganglion. Often no causal factors can be adduced. The sexes are equally affected. Hereditary influences are not uncommon. It is much more common in cold and damp climates, than in southern and dry countries. Any debilitating influences, such as overwork, general ill-health and specific fevers, especially influenza, may precede the onset of the malady. Peripheral irritation of the branches of the nerve from dental caries, or periostitis, or from injury, or any other long-lasting painful affections in the distribution of this nerve, may be the starting-point of true neuralgia.

Symptoms.—The chief feature of the malady is pain, which may be general throughout the area of distribution of the nerve, but which is more commonly confined to one of the three divisions of the nerve and often to one branch of a division. It is characteristic for the pain of neuralgia to commence locally, and subsequently to spread in each attack and gradually, in the course of the disease, permanently to invade a larger area. Two different kinds of pain occur, the sharp and paroxysmal, and the dull and continuous pain. The paroxysmal pains are sudden in onset and in cessation. They have a lightning-like character, and are described as piercing, knife-like, or as if the affected region were penetrated by red-hot wires. Often quite spontaneous, these pains may be brought on by touching the surface, by a cold draught, by movement of the face and jaw, or by the act of swallowing, and in this last condition mastication and deglutition may become so difficult as to render feeding the patient a matter of great anxiety. When the paroxysms are occurring in a severe case the patient remains for a period, which may be from a few minutes to several hours, paralysed under the fear of the pain, unable to move a muscle lest a spasm more dreadful than the last should occur. The paroxysmal pains are usually followed, if severe, by a more lasting dull continuous pain, often of a boring character, and sometimes such pain becomes absolutely continuous for months and years. The skin over the affected region is sore and tender after the paroxysm, and the patient may be unable to bear brushing the hair or shaving the face. The pain may be of every degree of severity, from mild momentary starts, such as occur in many young people when run down, to continuous incapacitating

pain, interrupted only by excruciating attacks of agony which render life a piteous burden. The distribution of the pain may be anywhere or everywhere in the distribution of the trigeminal nerve. It must be especially remembered that this nerve supplies the middle ear, the Eustachian tube and the region of the tonsil. Pain in the ear and low down in the pharynx is not uncommon. The lightning-like onset of the agony often causes convulsive spasm of the face and of the body and limbs, and from this feature the names "tic douloureux," "spasmodic neuralgia," and "epileptiform neuralgia" arose. The tender points of Valleix are constantly present during the attack, and for some little time after. When the first division is affected the tender points are found above the supra-orbital notch, over the external angular process, on the upper outer aspect of the nose, and on the globe of the eye. When the superior maxillary division is affected the chief tender point is over the infra-orbital foramen, while other points may be found over the points of exit of the temporo-malar nerves and in the roof of the mouth. When the third division of the nerve is involved, the chief tender points are over the mental foramen, the side of the tongue, and just in front of the external auditory meatus. When the third division is affected unilateral furring of the tongue, which always occurs when the pain is present and which does not seem to occur with organic lesions of the fifth nerve, nor constantly in any other malady except neuralgia, is seen. Vasomotor and secretory disturbances are common. During the paroxysms, tears and saliva may flow in abundance. The trophic changes which have been described in the skin are usually the result of rubbing during attacks of pain, or of the application of heat or liniments. Local greying of the hair however, does undoubtedly occur. The clinical picture of trigeminal neuralgia is completed with varying degrees of general physical ill-health, mental apathy and depression, which occur in proportion to the frequency and severity of the attacks, the presence of continuous pain, the ability to take food and to sleep, and the possibility of taking any interest in life. It is surprising in England how few of the sufferers from severe neuralgia become habitual drug-takers.

Course.—In patients under the age of 40 years the malady is often transient and is completely and permanently recovered from, though even at this age cases occur which are only amenable to surgical interference. But when the malady commences after the age of 40 years, it is the rule for it to become progressively worse. The paroxysms become more severe, and occur at shorter and shorter intervals, continuous pain sets in, sleep and the taking of nourishment become difficult, and useful life becomes more and more restricted.

Diagnosis.—There should be no difficulty in making a correct diagnosis if proper care be taken. In the first place, all local cause for pain in the peripheral distribution of the trigeminal nerve should be excluded. The teeth should be most carefully examined and the jaws skiagraphed for any concealed disease, which should be put right if present. Organic disease of the fifth nerve can be excluded by the facts that such disease cannot long exist without signs of loss of function, which never occur in neuralgia. Diminution of sensibility, which is first marked perhaps by increased tolerance of the conjunctiva and cornea to touch, and weakness of the musculature with deviation of the chin on opening the jaw, and diminution of taste

are certain signs of a local organic lesion. Moreover the pain of neuralgia, with its lightning onset and cessation, is hardly imitated by any pain of organic origin. Ocular conditions, such as glaucoma, which may give rise to agonising pain can hardly be mistaken for neuralgia.

Treatment.—Having in the first place seen that all possible causes of local irritation in the region of distribution of the fifth nerve are absent, or, if present, adequately dealt with, it is essential to improve the nutrition and general physical health with tonic, dietetic and hygienic treatment, and such remedies alone will often cure slight cases. *Tr. gelsemii* in doses of from 10 to 20 minims thrice daily is an admirable remedy, and arsenic is a useful adjuvant. All the analgesic antipyretics of the coal tar series are of great value, not only as immediate relieves of pain, but also as curative agents, and among these *aspirin* is most important. In cases where malaria has been recently present, quinine should never be omitted. In very severe cases, and when operation is to follow, morphine is an invariable temporary relief to the pain. But if persisted in, the beneficial effects of moderate doses soon disappear. In every case except in old subjects, a thorough trial of the above treatment should be made over a sufficient period to make a competent judgment of its efficiency or inefficacy, as the case may be. When failure is met with, and in old subjects, who will be found to respond little if at all to such treatment, operative relief should be sought. In the first place, the injection of alcohol should be performed, and if this fail, as it sometimes does, on account of anatomical peculiarities of the individual, recourse should be had to the operation for dividing the fifth nerve proximal to the Gasserian ganglion. The method of alcohol injection consists of introducing a few minims to a drachm of 80 per cent. pure alcohol by means of a long, hollow needle and syringe into the region of the Gasserian ganglion, via the foramen ovale. The foramen ovale is reached by a lateral route, by introducing the needle about an inch in front of the external auditory meatus and between the zygoma above and the sigmoid notch of the mandible below. The direction taken is almost at right angles to the surface, but if anything a little upwards and backwards. The right direction, however, varies with individual skulls. In edentulous subjects, there may be little or no room for the passage of the needle between the sigmoid notch and the zygoma, and this difficulty is avoided by keeping the mouth open. The alternative route is an antero-posterior one, from the front of the face to the foramen ovale, directed somewhat inwards and skirting the lateral aspect of the superior maxilla. The needle is introduced just below the point of the malar bone. This operation should be performed under morphine and scopolamine, and not under general anæsthesia, for unless the patient is sufficiently conscious to describe his sensations during the procedure, and to respond to tests for the trigeminal anæsthesia which it is essential to produce, it is impossible for the operator to be sure either of what he is doing or whether he has succeeded in his endeavour to destroy the ganglion. The sign of success is the appearance of complete anæsthesia over the whole distribution of the fifth nerve, and complete motor paralysis. Even when such success is not accomplished, great relief of the pain may occur. In bilateral cases complete paralysis of the jaw on both sides must be avoided by attempting first a partial injection on the less severe side, which may relieve the pain without producing lasting paralysis of the jaw on that side,

and then, when the paralysis of the jaw has recovered, to attempt a complete injection upon the more severe side. We have in several cases effected complete relief in this way, without causing any difficulty in mastication. The permanence of the effect of alcohol injection varies, sometimes lasting relief is obtained; more often, after a period which varies from months to years, some return of the pain occurs from partial recovery of nerve elements which have escaped destruction. The alcohol injection can, however, be repeated, and in this way permanent relief obtained. This operation is a minor one from the patient's point of view—it causes a minimum of suffering, and is soon over. It is, however, a most difficult procedure for the operator, and requires great skill and experience. While absolutely devoid of risk in skilled hands, alcohol injection should never be undertaken by one who has not special training in its performance. The radical operation produces brilliant and final cure. It is, however, a severe procedure, not unaccompanied by risks, and it produces unsightly sinking in of the temporal fossa. The ganglion is reached by removing the calvarium over the temporal fossa as low as the zygoma, lifting the dura mater from the middle fossa of the skull, defining the inferior division of the fifth nerve and following it back to Meckel's space, which is opened up and the nerve divided behind the Gasserian ganglion.

FACIAL HEMIATROPHY (PARRY-ROMBERG SYNDROME)

Definition.—A peculiar malady confined to some part of the distribution of the trigeminal nerve, or rarely extending from thence on to the area of sensory distribution of the upper four cervical nerves. It is characterised by a progressive atrophy of all the tissues, skin, subcutaneous tissue, muscle and bone, without sensory loss or paralysis. It comes to an arrest after a few years. No pathological condition has been discovered to account for the atrophy.

The disease may commence in childhood even as early as the second year, but it is most commonly started in early adult life. Females are much more often affected than males. Sometimes it appears without any exciting cause, but more often some injury of not very severe nature, such as a blow on the face, fracture of the alveolar processes during dental extraction, or other surgical procedure, seems directly to have initiated the atrophy. It has been known to follow both scarlet and typhoid fever.

Symptoms.—The atrophy may be distributed over the whole area of the supply of the trigeminal nerve, or, as is more usual, may be confined to one or more of its branches. In general atrophy, a gradual diminution in the bulk of the whole side of the face is the first indication of the disease. When the disease is confined to one of the three great divisions of the nerve, the atrophy usually commences in one spot, commonly on the cheek just below the malar bone, where the skin becomes thin and pale from loss of pigment, and the down falls out. The submalar fat disappears, leaving an unsightly hollow. The atrophy spreads to the side of the nose, where the cartilages and bones become gradually smaller. The jaws gradually decrease in size upon the affected side, until they are too small to hold the teeth, which are actually pushed out by the decreasing size of the tooth sockets. The half

of the tongue upon the affected side decreases in size, and thereby is rendered sickle-shaped. Even the eye may be remarkably lessened in size. The upper part of the first division of the fifth does not seem so liable to involvement, for it is rare to see any diminution of the size of the forehead, or dropping out of the hair of the scalp. S. A. K. Wilson has, however, recently shown a case in which the first division alone was affected. The ear, however, may be remarkably reduced in size. The skin in the end becomes very thin and parchment-like. The ultimate condition in well-marked cases is very striking and unsightly. The facial appearance is as if the face were made up of two unequal halves from different individuals, and this inequality may reach a most grotesque degree in cases where the disease has commenced in infancy and where the effect of growth upon the normal side of the face has added to the disparity. The normal side has the fullness of youth and the other the wrinkles and atrophy of age. The atrophy not uncommonly affects the ear and may spread on to the side of the neck over the areas of the first three cervical nerves. J. P. Martin has recently shown a case in which all three divisions of the fifth nerve were severely affected and in which the atrophy extended as low as the fourth dorsal distribution, the folds of the axilla and the mamma being conspicuously affected. The upper limb, however, escaped. There is no impairment of sensibility except some blunting in a few of the cases where the skin has wasted to less than a tenth of its normal thickness and become like parchment. Notwithstanding that the muscles diminish in size with all the other soft tissues and bones of the face, they do not in any way lose power or cease function. No pain or subjective sensation of any kind accompanies the atrophy, which commences insidiously and progresses steadily for some years, and then becomes finally arrested. The most marvellous feature of this malady is that it is not an arrest of growth but the reverse; there is an ever-progressive diminution of hard bones and soft tissues alike, their conformity and function being preserved meanwhile. The malady is associated with no ill effect other than the very ugly and unsightly facial appearance.

Diagnosis.—This is simple, as there is no other cause of smallness of one side of the face, involving bones and soft tissues alike, except congenital facial asymmetry, which is at once distinguished from this disease by the history of atrophy in a previously normal face and by the remarkable thinning of the skin, wasting of the fat and wrinkled appearance.

Treatment.—The only treatment is cosmetic, to improve somewhat the appearance of the face, by the injection of semisolid paraffin, to replace the fat and fill the unsightly submalar hollow.

THE SIGNS OF LOCAL LESIONS OF THE BRAIN

The localisation of the position of lesions within the nervous system depends upon the presence and recognition of local signs, indicative of the impairment of function of nervous elements of which the function is definitely known. Sometimes localisation may be deduced with relative accuracy by the absence of local signs, which then indicate that no elements with definitely known function are involved. Inasmuch as the focus of disease involves nuclei or tracts with well-defined function, definite symptoms appear and

localisation will present no great difficulty. For example, in the cerebellum of which the functions are known, in the brain stem where many conducting tracts and nuclei of known function are crowded together, and in the basal ganglia whose functions are becoming definitely known, a lesion can hardly exist of any size without causing easily recognisable localising signs. On the other hand, in the cerebral hemispheres, where localisation of function is mysterious and where so many "silent areas" exist, regional diagnosis is much more difficult and is sometimes impossible. It may be said that it is only when conducting tracts of known function are involved on their way to the cortex, or at their impingement upon the cortex, that the more definite signs of hemispheric localisation appear. If then in a case where general signs of a local intracranial lesion are present, all localising signs are absent, it may be deduced with certainty that the lesion is in the cerebral hemispheres, and that it does not involve the regions upon which the visual and sensory tracts impinge, nor the region from which the pyramidal tract emanates, nor those deeper structures through which these tracts pass. The importance of localising signs varies greatly with the stage of the illness at which they appear. Those which appear early are all important, those which appear late, when increased intracranial pressure and evascularisation have disturbed both the anatomical relations and physiological activity of many regions of the brain, are of little localising value.

HEMISPHERES GENERALLY.—Diminution or disappearance of the abdominal reflexes upon one side is an indication that a cerebral lesion is in the opposite hemisphere. This sign may be the earliest organic sign to appear and the first localising sign of a lesion in the cerebral hemisphere. It is of great importance. An extensor response in the plantar reflex is of similar significance. Both these signs actually depend upon slight disturbance of the pyramidal system, but they occur with lesions far distant from that structure.

Prefrontal lobes.—Localisation is often difficult and uncertain. Mental changes such as alterations of character, temperament and tastes, loss of reserve, inattention, loss of concentration, loss of memory for recent events and, in a few cases, grandiose ideas and loss of all perspective occur. With large lesions, delusions, stupor and dementia may supervene. If the lesion involve the left third and second gyri, definite localising signs—verbal aphasia and agraphia may appear, and Jacksonian fits commencing with aphasia may be met with. Adie and Critchley have described a "grasping" reflex, which they deem highly characteristic of pre-frontal lesions. When the palm of the hand on the opposite side is stroked with an object, the fingers involuntarily close upon the object.

When the lesion affects the orbital lobule, there may be anosmia. This is of greater localising value if it is unilateral. There may also be pressure upon the optic nerve on one side, with corresponding visual defect. Lesions of this region, and especially tumour, are apt to cause slight impairment in the functions of the ascending frontal or motor convolution, which lies immediately posterior, and slight signs of hemiplegia, especially weakness of the face, are most important. Tremor of the homolateral limbs has been observed. Incontinence of sphincters of the mental variety may occur as in temporal lesions.

Ascending frontal convolution (motor area).—Hemiplegia is the char-

acteristic sign of local lesion of this region. On account of the wide extent of the ascending frontal gyrus it is rarely involved to its entire extent in one lesion. Partial involvement produces monoplegia of face or of arm or of leg, according to the position of the lesion. Conjugate deviation of the head and eyes may be met with, away from the side of the lesion, if this be irritative, as at the commencement of an apoplexy, or of a local fit, or towards the side of the lesion if the lesion be paralyzing. The two forms of conjugate deviation often follow the one after the other, from the same lesion which is at first exciting and afterwards paralyzing. Conjugate deviation of the head and eyes is seen with acute lesions rather than with those of slow development. Jacksonian attacks are frequent and take the form of local convulsion, followed by a varying degree of temporary weakness (*Todd's paralysis*). The more deeply the lesion extends into the sublying white matter, the more does it tend to produce an extensive hemiplegia, since the pyramidal fibres converge from the cortex towards the capsule. Loss of localisation to sensory stimuli is not infrequent from simultaneous involvement of the neighbouring post-central convolutions.

Parietal lobe.—Astereognosis is the all-important localising sign of lesion in this locality. It consists in the inability to recognise the nature of an object placed in the hand by its shape, size and consistency. The summation of all the sensations produced by the presence of the object in the hand, by which we instantly recognise a well-known object, is lacking. Cutaneous sensibility, and particularly tactile sensibility, may be impaired. Localisation may be inexact. The appreciation of active movement and passive position is apt to be faulty, and some ataxy may result therefrom. Trophic changes may be observed in the periphery of the limbs, and lesions in this situation seem to be responsible for the arrest of growth which is seen in cases of infantile hemiplegia. Jacksonian attacks, consisting of a peripheral sensory aura, sometimes followed by convulsions, occur. These localising signs are confined to the opposite side of the body.

Occipital lobes.—Lesions of the cuneus and region of the calcarine fissure on the mesial aspect of the occipital lobe result in hemianopia of the opposite field, but central vision escapes. If the lesion is limited above the calcarine fissure a quadrantic hemianopia of the lower field results, and if the lesion is below the calcarine fissure the quadrantic hemianopia resulting is of the upper field. Since central vision is represented at the posterior pole of the hemisphere, a lesion of the posterior pole causes central hemianopic scotoma, vision in the periphery of the field remaining intact. Consequently a bilateral lesion of both posterior poles will result in bilateral central scotoma, and a bilateral lesion of the calcarine region will produce blindness of both peripheral fields, central vision remaining intact. If the lesion extends deeply into the occipital lobe so as completely to sever the optic radiation to the occipital cortex, complete hemianopia, affecting both the central and peripheral part of the visual field, will occur. The hemianopias resulting from lesion of the occipital lobe are distinguished from those due to lesion of the optic tract by the fact that in the former the pupil reacts to light thrown on to the blind part of the field (*Wernicke's hemianopic pupil phenomenon*). On the outer surface of this lobe, a lesion extending deeply on the left side may sever the connection of the visual centres with the speech centres, and so produce word-blindness. Such a lesion is usually situated at the

junction of the left occipital and temporal lobes. Jacksonian attacks are often of great value in occipital localisation, and take the form of visual hallucinations, often accompanied by transient hemianopia.

Temporal lobe.—The uncinate and hippocampal regions of this lobe are the cortical seats for taste and smell, and the localising symptoms which are rarely absent when lesions in this region exist are Jacksonian attacks in the form of hallucinations of taste and smell, nearly always of an unpleasant nature. The hallucination is often immediately followed by a "dreamy state," during which smacking movements of the lips, or champing movements of the jaw, or spitting may occur. Experience seems to prove that all highly organised hallucinations, whether auditory, visual or psychic, when occurring from organic lesion of the brain, point to a lesion in the uncinate region. The senses of taste and smell are not lost from a unilateral lesion of this region, since they are bilaterally represented in the cerebral hemispheres. The outer surface of the temporal lobe is concerned with hearing, but from the complete semi-decussation of the auditory path, unilateral lesions never produce detectable deafness. On the left side, however, the temporal lobe is concerned with speech, and destruction results in serious disorder of speech functions. Inasmuch as lesions of this region are situated far forward toward the insula, they result in "verbal aphasia," or towards the centre of the convexity of the temporal lobe, in amnesia, or lack of recall of words and "word-deafness," while if towards the posterior limits of the lobe they produce "word-blindness" from severance of the visual path to the speech region. Deeply seated lesions isolating the speech region from the incoming auditory path produce jargon aphasia. Jacksonian attacks, consisting of auditory hallucinations, which may or may not be followed by aphasia or by convulsions, may occur. Extensive lesions of the left temporal lobe cause much mental impairment. On account of the wide excursion which the optic radiation makes into the deep part of the temporal lobe in its course from the thalamus to the cuneus, homonymous hemianopia, especially of the upper quadrants, is very common in deep-seated lesions of the temporal lobes. The occurrence of incontinence of sphincters of a mental type is highly characteristic in some cases. When lesions extend deeply there may be a paresis of the opposite face for emotional movements, out of all proportion to the loss of volitional movements.

Corpus callosum.—Lesions of this region present the greatest difficulty in diagnosis, but if the anterior part of this structure is affected, there may be apraxia of the limbs, and when the splenium is involved we have observed several cases in which loss of memory and amentia, in the absence of other local signs, were so conspicuous and came on so early as to enable us to make with certainty a correct local diagnosis.

Internal capsule.—In this region, the chief motor tract is condensed into a small space, and is situated immediately in front of a narrowly localised sensory tract, while not much farther posteriorly, the visual path enters the thalamus. Lesions of this region therefore produce severe and widely-spread hemiplegia of the opposite side, often associated with hemianæsthesia and not infrequently with hemianopia of the opposite side. From the proximity of the thalamus and corpus striatum, there is often involvement of these structures in a capsular lesion, with appearance of the characteristic, spontaneous involuntary movements and sensory loss.

BASAL GANGLIA.—*Optic thalamus.*—A very characteristic clinical picture results from destruction of this structure which is termed the “thalamic syndrome” of Dejerine and Roussy; there is hemiparesis with spontaneous involuntary movements of the opposite side, which may be of the nature of tremor, intention-tremor, choreic, athetotic, dancing or irregular movements. Most of the post-hemiplegic involuntary movements are due to a lesion of the thalamus. In addition, there is hemianæsthesia, often with a characteristic hyper-sensitivity to aggressive stimuli, such as tickling, cold water, etc., which may produce agonising distress. Sometimes spontaneous, constant and unrelievable pain occurs on the opposite side. Emotional movement of the opposite face may be impaired much more than is volitional movement.

Corpus striatum.—Paresis of the opposite side with spontaneous involuntary movements also occur with lesions in this situation. These may be of a rhythmic tremulous order, as in paralysis agitans, or athetotic (Klumpke syndrome), and, when the lesion is situated in the posterior part of the lenticular nucleus, both athetotic and choreic.

Region of the optic chiasma and pituitary body.—The most common lesion in this region is pituitary tumour, which involves the optic chiasma, at first in the middle line posteriorly, and subsequently advancing forwards. Three sets of symptoms are likely to arise—(1) Those due to dyspituitarism, such as acromegaly or gigantism if there is hyper-pituitarism, or Fröhlich’s dystrophia adiposo-genitalis, or Lorrain infantilism if there is hypopituitarism. Adenomatata of the pituitary body produce hyperpituitarism if they contain eosinophile cells, and hypopituitarism if such cells are absent. (2) Those due to the pressure upon the optic chiasma, which commence as bitemporal paracentral scotomata, which enlarge as the compression extends until a complete bitemporal hemianopia results. It cannot be too strongly impressed upon the reader that the pattern of the visual field defect is determined by the position of local pressure upon the visual paths, and that any variety of defective field may occur. While bitemporal loss is the most usual, yet when the pressure is far forward, unocular hemianopia, blindness of one eye, and central scotoma are all of common occurrence, and when the pressure is farther back than usual homonymous hemianopia is frequently seen. And (3) those due to the general effect of the tumour, namely, headache and vomiting. Optic atrophy is the rule, as the result of the direct pressure, and not papilloedema. It is to be remembered, that all pituitary cases are prone to headaches and subject to fits.

Region of the falx cerebri.—Lesions of this structure are likely to affect both hemispheres equally. Tumours opposite the paracentral lobules cause bilateral crural monoplegia, and those in the posterior region of the falx, bilateral hemianopia. Thrombosis of the superior longitudinal sinus produces widely spread bilateral softening of the hemispheres, with double hemiplegia.

Corpora quadrigemina.—The oculo-motor nuclei lie on either side of the aqueduct of Sylvius, and lower down on either side of the middle line, in the floor of the upper part of the fourth ventricle, and lesions of this region cause nuclear ophthalmoplegia—that is, paralysis of both eyes in terms of the conjugate movements upwards, downwards or laterally. From before backwards, lesions of this column of oculo-motor nuclei will produce Argyll Robertson pupils, paralysis of accommodation, paralysis of upward, downward

and lateral movements respectively. Immediately ventral to the oculomotor nucleus and decussating beneath it, lie the superior peduncles of the cerebellum, involvement of which causes bilateral ataxy of limbs and trunk. Lesion of the dorsal part of the quadrigeminal layer produces a characteristic syndrome of nuclear ophthalmoplegia with bilateral ataxy, which is termed Nothnagel's syndrome. The pyramidal fibres for the face leave the pyramidal tract in this region of the tegmentum and may here be involved alone, causing bilateral spastic paralysis of the face. In the ventral portion of this region of the brain stem are the crura cerebri with the third nerve, perforating each crus to emerge upon its inner side, and the optic tract running round the crus from the geniculate bodies to the optic chiasma. A lesion of one crus will cause hemiplegia of the opposite side and paralysis of the third nerve on the same side. This pathognomonic localising combination is known as Weber's syndrome. Situated a little more dorsally, a lesion of the crus will produce ophthalmoplegia of one eye with tremors and inco-ordination of the opposite limbs. This is known as Benedikt's syndrome. Extension of a lesion outwards from the crus will cause tract hemianopia, in which the half-fields are completely involved, with no light reaction from the blind fields. Interference with the fillet may cause hemianæsthesia.

PONS AND MEDULLA.—In these regions the motor and sensory tracts, the cerebellar peduncles, the cranial nerve nuclei, and the outgoing cranial nerves are closely packed together, and the signs resulting from destruction of these will be varying combinations of spastic paralysis, ataxy and sensory loss—from interference with the long conducting tracts—in the body and limbs, with nuclear and peripheral nerve palsies and anæsthesia in the region of the face. If the lesion is unilateral the body and the face will be affected on opposite sides, causing the “crossed paralyses” or “alternate paralyses” of lesions of the brain stem, of which facial palsy with contralateral hemiplegia, trigeminal palsy and sensory loss, and vagal palsy with contralateral hemiplegia are usual varieties. From the smallness of the brain stem lesions most often involve both lateral halves of this structure, and bilateral symptoms result. Lesions of the brain stem below the oculo-motor nuclei, cause small pupils (pontine myosis) from cutting off of those nuclei from the spinal cord, whence the tonic dilator of the pupil—the cervical sympathetic system—emerges. Glycosuria may occur from interference with the vasomotor centre, and involvement of the respiratory centre is frequent.

CEREBELLUM.—Lesions of the lateral lobe of the cerebellum produce a series of physical signs which are so characteristic that they can hardly be overlooked in any patient who is well enough to respond to the necessary tests. These signs are not always all of them present in any given case, nor in one patient at any given time. Cerebellar signs often vary in degree from time to time. They are as follows :

1. Nystagmus, with a long-range slow movement on conjugate deviation to the side of the lesion, and a short-range much quicker movement on looking in the opposite direction. Lesions of the middle lobe give a nystagmus equal in both directions, and sometimes nystagmus may be absent.

2. Hemiataxy on the side of the lesion. It is dynamic ataxy ; that is to say, it becomes obvious only when the patient moves, and is due to the loss of postural tone, of which the cerebellum is the central organ, and which is essential to the accurate co-operation of the synergic muscles. There is no

loss of the muscular sense or sense of position, and, therefore, no change on closing the eyes, and Romberg's sign is absent.

3. Loss of unconscious balancing movements. No attempt is made unconsciously to recover balance when this is upset. It is done consciously, and is therefore late and slow, and the patient can be pushed over easily. This sign is often conspicuously seen when the patient is walking, when the arm of the normal side makes the usual to and fro movements with each step, but the other arm, though hypotonic, hangs motionless. This sign is of the utmost importance when present, as a true indication of the side of the lesion.

4. Hypotonia or unusual flaccidity of muscles on the side of the lesion.

5. Dysdiadokokinesia or inability to perform any rapid alternate movements upon the side of the lesion. The test is easily performed by asking the patient to extend the arms with the fists closed, and rotate them rapidly. The inability upon the affected side becomes at once apparent.

6. Attitude. When standing or sitting, the patient naturally assumes a position in which the occiput approximates to the shoulder on the side of the lesion, and the face is turned slightly to the opposite side. The homolateral leg is slightly abducted so as to broaden the supporting base, the spinal column tends to be concave to the affected side, and the shoulder on that side is held higher and a little in advance of the opposite shoulder.

7. Gait. This is often described as reeling, staggering or drunken, but it is often slow and careful, though clumsy. The affected leg makes less excursion than the sound leg, as if it were not trusted. When attempting to walk in a straight line, the patient tends to walk in a curve towards the side of the lesion, and he tends to fall to that side.

8. Unwillingness to look to the side of the lesion, although the ocular movements are perfect, may be a conspicuous and important sign.

9. In a few cases a peculiar strabismus known as the "skew deviation" is seen—one eye looks up and in, and the other down and out.

In acute and irritative lesions of the cerebellum, such as vascular lesions, severe vertigo, forced movements of rotation which always turn the patient so that his face on the side of the lesion is in contact with the pillow, and severe vomiting occur. When the lesion is in the middle line, and especially when it extends into both lateral lobes, the signs are bilateral, and there may be ataxy of articulation, resembling that of disseminate sclerosis. The deep reflexes are variable: at one time diminished, at another exaggerated. The superficial reflexes are not affected; the plantar reflexes are of the flexor type.

10. Lateral recess. The angle formed by the posterior surface of the petrous bone and the tentorium is a common situation for neurofibromata which grow usually from the eighth nerve, but occasionally from the seventh and from the fifth nerve, and press into the lateral lobe of the cerebellum. A highly characteristic clinical picture results, of slowly oncoming nerve deafness, unilateral signs of cerebellar involvement and some peripheral facial spasm, to which are sometimes added facial weakness and tinnitus. Such tumours are not of great size, and therefore headache and papilloedema are often absent or occur late.

INTRACRANIAL TUMOURS

Under this heading are grouped all new formations which encroach upon the intracranial space, and which produce the familiar pressure symptoms and local symptoms of tumour, though some of these are not, strictly speaking, neoplasms.

Ætiology.—The brain is actually the most common seat of new-growth among all the individual organs of the body. At the National Hospital, London, 500 cases were admitted in 9 years, and Cushing reports a similar number in his clinic in the same period.

Age.—Cerebral tumour may occur at any age, but it is relatively uncommon in the very young and in the very old. It seems to be considerably more common in the female sex. The relation between cephalic trauma, and the first appearance of symptoms of cerebral tumour, is one which occurs much too often to be ignored, though it is likely, in many of the cases in which this relation exists, that the blow on the head has simply served to bring a pre-existing tumour into symptomatic prominence, either by causing œdema or hæmorrhage in its substance, or vicinity. It must be remembered in this connection that a cerebral tumour may exist for long periods without definite symptoms. For example, a patient of ours had suffered with rare attacks of epilepsy, commencing with a complicated visual aura, for 17 years. After natives in the West Indies had attempted his assassination by bombarding his head with cocoanuts, many of which struck him, and rendered him unconscious, he developed urgent symptoms of intracranial tumour without localising signs. On the history of visual fits of 17 years' duration, Sargent explored the corresponding occipital region and came immediately upon a large growth of the right occipital convexity.

Pathology.—A short account of the nature of intracranial tumours in order of the frequency of their occurrence here follows :

Gliomata.—These are by far the most common of brain tumours. They are essentially ectodermal tumours, taking their origin from any part of the primitive ectodermal tube, its developments and vestiges, which ultimately make up the central nervous system. They may occur, for example, in the remote coccygeal region, from rests there remaining of the primitive neural tube. The gliomata must therefore be strictly separated from sarcomata, for the latter arise from mesodermal, and not from ectodermal structures. The glioma grows from the brain substance, and is usually a soft, rapidly-growing very vascular tumour, and in its vessels degenerative processes are liable to occur, causing thrombosis and hæmorrhage, while in its vicinity and substance acute œdema is very prone to occur. The importance of these three associates of cerebral tumours, acute œdema, hæmorrhage and thrombosis, and especially of acute œdema, can hardly be overestimated in the causation of increased intracranial pressure, sudden appearance or exacerbation, or sudden remission of symptoms, in cases of cerebral tumour. Acute œdema, occurring in the vicinity of a previously symptomless and structurally obsolete tumour, no larger than a marble, has caused death within a week of the first symptom twice in my experience. Gliomata are often diffuse with no sharp limit separating them from normal brain tissue. They may grow between and displace the nerve elements, causing

little interference with their function, until degeneration or vascular lesions occur in the tissues of the tumour. On the other hand, it is important to remember they may be strictly encapsulated. In the absence of degenerative changes and of vascular lesions within its substance, the glioma resembles the greyish red of cortical tissue in colour, and in consistence it is not unlike the normal brain, so that when not encapsulated it may be very difficult to distinguish from the surrounding brain tissue, when exposed at operation or at autopsy. The glioma, like other brain tumours, does not metastasise, but when it is exposed to the cerebro-spinal fluid by rupture of its surface, grafts may be washed off, which may cause fresh growths in the course of the cerebro-spinal fluid, and especially in the pockets of the nerve roots in the spinal theca. The same event may occur when other primary brain tumours become similarly exposed to the cerebro-spinal fluid.

Endotheliomata.—These are the next most frequent of all the true intracranial tumours. They grow commonly from the endothelial lining of the meninges, much more rarely from the endothelium of blood and lymph vessels; but they frequently become deeply embedded in the brain substance, though they are always strictly limited from and detachable from it. They may involve and cause great thickening and deformity of the skull case. These tumours are intrinsically benign. They grow slowly, and in Cushing's opinion are the most favourable of all for operative removal.

Sarcomata.—These tumours are firmer in structure than the glioma, and are always strictly limited and encapsulated. Not infrequently they are of cranial origin, and arise in the diploë, and may enlarge the skull externally, and give evidence of their presence and situation by being palpable and visible upon the surface of the skull. Sarcomata found within the brain substance are usually of metastatic origin, and show the characters of the original tumour.

Carcinomata.—These occur as metastases most commonly from mammary cancer: they are often multiple and frequently show cystic degeneration. Primary carcinomata of the lung and of the kidney are particularly prone to give rise to metastases in the brain.

Cholesteatomata.—Sometimes called "mother of pearl" tumours, on account of their glistening appearance, are found in connection with the basal meninges. Their origin is uncertain. They are either of slow growth, or run a symptomless course. They consist of a greasy, greyish, friable and more or less laminated mass, made up of layers of a closely packed mosaic of flat polygonal cells. The tissue is necrotic, and contains no blood vessels.

Among the rarer tumours of the brain may be mentioned dermoid tumours, teratomata, chordomata, which arise from rests of the anterior end of the primitive notochord and are found below the base of the brain, lipomata, fibromata, neuromata, neuroblastomata, consisting actually of undifferentiated nerve cells, enchondromata, angiomas and psammomata.

Cysts.—Cysts of the following nature may occur—(1) Congenital interpeduncular or pituitary cysts, which arise from a pharyngeal rest in connection with the development of the pituitary gland; the resulting signs are those of pituitary insufficiency, together with those of pressure upon the optic chiasma. (2) Simple serous cysts which are presumably the remains of soft tumours, which have become completely degenerated. (3) Tumours

containing cysts, presumably on the way to the formation of the above. (4) Blood cysts, the rare results of hæmorrhage which has become arrested. (5) Cysts which result from softening after embolism and thrombosis. When occurring in the young, these cysts may lose every trace of their original origin, and form thin-walled cavities, containing colourless fluid, often extending from the ependyma to the pia mater, and involving the whole thickness of the pallium. They are termed "porencephaly." (6) Cystic distension of the ventricles from obstruction, which forms local or general hydrocephaly. These are met with in connection with tumours in any situation and result from adhesive meningitis, particularly syphilitic meningitis. (7) Dermoid cysts. (8) Parasitic cysts, of which the more common is the bladder worm of the tapeworm, *Tænia solium*, which is called, on account of the thickness of its wall, *cysticercus cellulosæ*. They are usually multiple, and choose the region of the fourth ventricle as their site of predilection. They may be multiple in the basal meninges, and constitute a "cysticercus meningitis." It is usual for these cysts to shrink and to become calcified and obsolete in from 3 to 6 years. Less commonly, the hydatid of *Tænia echinococcus* is found. It is usually single, may reach a large size and present the signs of a slowly growing tumour with eosinophilia.

Infectious granulomata.—Tuberculomata are more common in the young; but they may occur at any age. They vary in size from that of a millet seed to that of a hen's egg, and are more often found in the posterior fossa of the skull than above the tentorium. When large, coagulation necrosis and caseation occur in the centre, and on section the tumour presents a dry yellowish crumbling or even diffuent centre, with a greyish-red peripheral growing zone, where are located living tubercle bacilli and actively growing tubercles. The tuberculoma has an important aspect in connection with operation for extirpation. They are often situated favourably for extirpation, yet in every case where this operation has been performed the patient has succumbed to tuberculous meningitis, often after recovery from an apparently completely successful operation. Such a tumour recognised on decompression should be left severely alone.

Syphiloma.—This is not a common intracranial tumour. It grows most commonly from the meninges, and is therefore a surface lesion, though it may burrow deeply in the brain tissue. It is most commonly found above the tentorium. It is occasionally very hard in consistency, and tends in many cases to scar and become obsolete. It is sometimes impossible to distinguish this tumour from a tuberculoma without the aid of the microscope and the serum reaction.

Actinomycomata and tumours from streptothrix infection occur in very rare cases.

Symptoms.—An intracranial tumour may produce symptoms, either by raising the intracranial pressure (general symptoms), or by involving elements of the nervous system, of which the loss of function can be exteriorised (focal symptoms). Such symptoms may be in large measure produced by certain secondary processes occurring in the vicinity of the tumour, such as œdema and vascular lesions, and the subsidence of acute œdema so produced may give rise to dramatic amelioration of symptoms under treatment. On the other hand, œdema of the brain may give rise to the clinical picture of cerebral

tumour, when no tumour exists, as was frequently seen from contusions, concussions and bullet wounds during the Great War. Further, a cerebral tumour may exist, even of large size, without raising the intracranial pressure, and without causing focal symptoms. Consequently no symptoms whatever arise, and the existence of a tumour is a post-mortem discovery. Or a tumour, after remaining latent perhaps for years, may give rise to the rapid development of symptoms, usually from the occurrence of oedema in its vicinity. It is owing to the occurrence of this oedema that tumours of small size may give rise to severe and rapidly fatal symptoms. Thus patients may present themselves with (1) Tumours which give absolutely no recognisable evidence of their existence, and are found post mortem—this event seems to be more common in advanced age, and in subjects with hard arteries; (2) tumours which give focal symptoms alone without evidence of increased pressure—this again is met with more often in advanced age, and when arterial disease is present; (3) tumours which give general manifestations of increased pressure, but no focal symptoms—these are always supratentorial in situation, and do not occupy those regions of the hemispheres with known and exteriorised function; (4) tumours which give typical signs both of increased pressure and of focal destruction—these are the most commonly occurring; and (5) the symptom-complex, both general and local, of tumour may be brought about by the occurrence of cerebral oedema from any cause when no tumour is present. It is important to realise that all tumours for a varying time after their commencement must fall into the first group of symptomless tumours.

GENERAL MANIFESTATIONS.—These symptoms are the result of raising of the intracranial pressure, and accordingly fail when there is no considerable raising. Therefore they tend to be conspicuously absent in the slowly growing tumours of the cerebello-pontal angle, in all tumours of the brain stem, in infiltrating tumours of the centrum ovale, and also for some unknown reason in advanced age and in the subjects of marked arterial disease. They consist in the following signs: Papilloedema, headache, vomiting, loss of vivacity and mental drowsiness, nasal irritation, giddiness, alteration of pulse-rate, of blood-pressure, respiration, and general convulsion.

Papilloedema.—This is by far the most constantly present of all the general manifestations. It is frequently present for a long time without headache or vomiting; but, on the other hand, it is rare to meet with either conspicuous headache or vomiting in the absence of papilloedema, and therefore this may be judged the earliest sign of increasing intracranial pressure. It fails to appear sometimes even with greatly increased intracranial pressure, as in hydrocephalus; but this is explained perhaps by the deterring effect upon its occurrence, of direct pressure upon the optic chiasma by a distended infundibulum. This is only seen in the hydrocephalus of children; in adults papilloedema is invariably present with active hydrocephalus. Papilloedema appears to be a stasis oedema of the nerve-head owing to the increased intracranial pressure forcing the cerebro-spinal fluid into the meningeal sheath which invests the optic nerve, and into the perivascular spaces which accompany the central vessels of the nerve. The nerve sheath becomes distended, and venous stasis occurs. On ophthalmoscopic examination the earliest changes are increased redness of the disk, distension of the veins, loss of distinctness of the nasal margin of the disk, with disappearance of the physio-

logical pit. As the process increases the whole margin of the disk becomes lost. It enlarges in area, and becomes visibly swollen and presents the appearance of a mole-hill as seen from above. The point of emergence of the vessels, at the centre of the disk, becomes buried by white exudation, which occurs also all over the disk, and taking a form determined by the radiating nerve fibrils, gives the disk the appearance of being striated in a radial fashion, like a chrysanthemum. A similar exudate may rupture the membrana limitans interna in little droplets at the macula, and coagulating as it comes in contact with the vitreous humour, produce the characteristic radially arranged macular figure of "macular fan," exactly similar to that seen in renal disease. The venous congestion of the retina leads to multiple hæmorrhages, which infiltrate along the radially arranged nerve fibres, and for this reason are flame-shaped. With the outpouring of much exudation, the disk becomes white. In the course of time the hæmorrhages become white flame-shaped scars, the whole disk contracts, the swelling disappears, and the disk becomes white, flat and atrophic, and distinguished only from that of primary optic atrophy by the scarred remains of the exudate at its edge, producing a fluffy outline like that of torn cotton-wool, along the vessels and at the centre. In the early stages of papilloedema, even though there be considerable swelling of the disk, vision may be little impaired. As the process increases however, in proportion to the degree of the swelling, to the amount of the exudate, and to the length of time the papilloedema has lasted in a severe condition, vision becomes impaired, and blindness results. Peripheral constriction of the visual fields, large pupil and dimness of vision, are the signs that, if the papilloedema be not speedily relieved, blindness will certainly result. Perfect vision may be retained for a time, even with a high degree of papilloedema. So important is papilloedema in the diagnosis of tumour of the brain, that it is necessary to bear constantly in mind all other causes which may give rise to it.

Papilloedema may occur in certain general intracranial conditions other than tumour. In meningitis it occurs as a late sign, and rarely before the tenth day, and as so many cases of meningitis do not survive so long, it is chiefly met with in the more chronic forms, such as tuberculous meningitis, and untreated cases of meningococcal meningitis. Abscess may also cause papilloedema; but it is by no means common in this condition. It may occur, too, in every variety of encephalitis, traumatic, poliomyelitic and lethargic, but only in exceptional cases.

Apart from intracranial disease papilloedema occurs in the following conditions: (1) Local conditions of the retina and optic nerves. In connection with tuberculoma of the retina in the neighbourhood of the disk, the most intense papilloedema may be found. Retrobulbar neuritis occurring close behind the disk may cause a similar condition, especially if it be of a syphilitic nature. Septic conditions of the ethmoidal cells, sphenoidal sinus, etc., may also cause papilloedema. In these three conditions the papilloedema is often unilateral, but in any of them it may be bilateral. (2) Renal disease may give a retinal picture of intense papilloedema, macular figure and hæmorrhages, sometimes quite indistinguishable from that due to tumour. This is often seen in the small white kidney of young subjects, and sometimes in small red kidney, but there is no form of renal disease, even including tuberculous, amyloid and lardaceous kidney, in which papilloedema has not been

observed. (3) Anæmic states of every kind sometimes give rise to papilloedema, even of severe intensity. This occurs most commonly in chlorosis. We have seen the sight lost in one eye, and seriously impaired in the other, as the result of atrophy after papilloedema in a severe case of chlorosis. As regards groups (2) and (3), it is essential to emphasise the facts that papilloedema, headache and vomiting may occur as a symptom-complex, both in renal disease and in anæmic states. More than one case of simple chlorosis has been decompressed for tumour. (4) Septicæmic conditions, and especially those producing arthritis. Of these infective endocarditis is the most common; but it has occurred with every form of septicæmic arthritis, and even in cases of acute rheumatism. (5) Further, papilloedema has been noted in connection with tumours, and with compressions and fracture-dislocations of the cervical cord, and also with acute myelitis.

The retinal changes in diabetes are always, and those in renal disease often, distinguishable from papilloedema resulting from increased intracranial pressure. In diabetes the change is essentially a hæmorrhagic retinitis from degeneration of vessels, sometimes with waxy-looking exudation in circinate patches; and in renal disease it is often a general oedema of papilla and retina, with hæmorrhages and white patches far away from the disc. The papilloedema resulting from increased intracranial pressure is always bilateral, though it may appear in one eye before the other, unless there be local pressure upon one optic nerve, which always delays or prevents papilloedema appearing in that eye. Otherwise, an earlier commencement upon one side is of no localising value whatever.

Headache.—It has been proved beyond dispute that the brain itself and the pia-arachnoid are insensitive to pain. It is probable that the headache of cerebral tumour is due to irritation of the terminations of the trigeminal nerve in the dura mater and bones of the skull from stretching and pressure, when the intracranial pressure is high. On the other hand, headaches due to abnormally low intracranial pressure, such as may follow upon the removal of cerebro-spinal fluid by lumbar puncture, etc., are probably due to venous congestion of the same tissues, or to stretching of dura mater by displacement. After destruction of the fifth nerve by Gasserectomy, headache never again occurs upon that side. The complete relief of headache after a successful decompression, is proof that pressure is the all-important factor in its causation. Small and slowly growing tumours therefore give rise to little or no headache, and this is especially true of the slowly growing tumours of the cerebello-pontal angle and of tumours of the brain stem. The latter, however, may cause obstruction of the aqueduct of Sylvius or of the fourth ventricle, with secondary hydrocephalus, and may then be productive of severe headache. The sensation may vary from a mere feeling of fullness of the head to the most agonising pain. It is more often remittent than continuous, and may be absent for long periods together. It is rarely localised to any definite region, except when the growth actually involves the bone, or when pressure has caused local thinning of the bone, when local pain and tenderness on pressure may occur. Usually it is referred indefinitely to the frontal or to the occipital or to the vertical region. When occipital it may be associated with pain and stiffness of the neck, and head retraction. This is due to a general pressure effect, and does not indicate any localisation. Headache may be entirely absent, even in the presence of severe papilloedema.

It may precede the development of papilloedema, but more often it is later in its appearance.

Vomiting.—Only two-thirds of all cases of intracranial tumour present vomiting as a symptom. It rarely occurs in the absence of the two chief signs of increased intracranial pressure, papilloedema and headache. When the headaches are severe, it may be associated with much nausea, and the attacks are often referred to by the patient as “bilious attacks.” Usually a result of increased pressure, it may be directly produced by lesions of the cerebellum, irritation of the vestibular nerve, and by the visual disorientation resulting from diplopia. As a symptom of intracranial tumour it hardly deserves the cardinal importance which has been assigned to it in most descriptions of this disease.

Loss of vivacity and mental drowsiness.—Even when intellectual capacity shows not the slightest impairment, there is from the first onset of symptoms a loss of vivacity, a slight heaviness and an absence of restlessness and irritability, which is of value in diagnosis. It is almost unheard of for a tumour patient to suffer from insomnia. As the symptoms increase, so do heaviness and drowsiness, though a perfect but slow cerebration may persist until the latest stages of the disease.

Nasal irritation.—The patients suffering from intracranial tumour at the National Hospital, London, during the past twenty-five years, have been noticed to rub their noses with such frequency as to render this circumstance a sign of real diagnostic value. The patients do not complain of nasal irritation, but will be seen frequently to rub the tip of the nose with the hand as if to relieve irritation. The sign seems to depend upon increased intracranial pressure for it occurs in a few conditions other than tumour, in which the pressure is markedly raised.

Giddiness.—Though this is an inconstant sign, it is often met with, and it may be due to vestibular irritation, when it amounts to an actual vertigo, or it may be a sense of general unsteadiness. It is met with most often in sub-tentorial tumours, but may be quite a general symptom when very high pressure exists. Vertiginous attacks comparable to those occurring in Ménière's disease, are only met with when acute lesions of the cerebellum are present. It is important that tinnitus occurs rarely as a sign of intracranial tumour.

Convulsions may occur as the result of the general disturbance of blood supply from high intracranial pressure, and are perhaps akin to asphyxial convulsions; they may occur irrespective of the situation of the growth. Such convulsions from general pressure occur late in the course of the case; early convulsions always have a localising value. They are of uncommon occurrence when the tumour is situated beneath the tentorium.

Blood-pressure, pulse-rate and respiration.—There is a compensatory increase of the blood-pressure for every raising of the intracranial pressure, so that the cerebral circulation may be kept going. The failure of such compensation is often the cause of the sudden death which occurs in tumour cases. The pulse-rate is in the inverse ratio of the blood-pressure, and, therefore, of the intracranial pressure, and the pulse is slower than normal, where pressure is above normal. Respiration tends to be slow, and when the physiological condition of the intracranial contents is much disturbed, it tends to become irregular, grouped, and may show the wax and wane of movements which bears the name of Cheyne-Stokes respiration.

Focal signs.—These have been fully described in the section upon the localisation of lesions of the brain. In connection with localisation, however, it is important to recognise certain possible sources of fallacy in making a diagnosis. Blindness from papilloedema prevents any localisation by means of the visual functions. Papilloedema usually causes at one stage great peripheral constriction of the visual fields which might be attributed to a bilateral lesion of the cuneus, and it may cause altitudinal hemianopia, i.e. blindness of the upper half of both fields, by sagging of the exudation into the lower part of the retina. Jacksonian epilepsy may occur in long-standing cases without any relation to the position of the tumour.

Paralyses of cranial nerves are serious pitfalls. They are of value in localisation when occurring early, and in association with alternate hemiplegias, and paralyses of the eighth, ninth, tenth, eleventh and twelfth are always of sure localising value. Paralysis of the sixth cranial nerve, perhaps, should always be disregarded as a localising sign for the following reasons: When the intracranial pressure increases from the presence of a growth, the first effect is that any superfluous cerebro-spinal fluid, of which there is normally very little, is expelled from the skull. Later, with further increasing pressure, since the only escape from the rigid skull is by its only opening, the foramen magnum, the medulla and cerebellum are pushed backwards towards the foramen magnum and come to fill up this aperture as with a cork. In all long-standing cases of increased pressure, the cerebellum will be found on autopsy, and especially when hardened *in situ*, to be deeply marked by the edge of the foramen, part of the cerebellum and medulla actually occupying the spinal cord. We have found part of the cerebellum pushed down in the form of a jelly bag, lying as low as the third cervical vertebra. Corking up of the foramen magnum in this way offers a marked impediment to the flow of cerebro-spinal fluid, and is a most important factor in the production of hydrocephalus, secondary to tumour. A vicious circle is set up, for the greater the blocking of the foramen magnum by the pushing back of the cerebellum and medulla, the greater is the retention and therefore the pressure above the obstruction. Bearing this in mind the immediately fatal effects which have followed lumbar puncture in long standing cases of high intracranial pressure will be at once understood and for ever avoided. This shifting backwards of the medulla and cerebellum will cause stretching of those cranial nerves attached to the medulla, in proportion as they are directed antero-posteriorly, and take a straight course between their attachments to the dura mater and their origin from the medulla, and of these the sixth nerves will be most affected, and afterwards the third, seventh and fifth in that order. These nerves will not only be stretched, but are subject to the increased pressure also, and they may accordingly cease function simply as the result of the increased pressure. Nor is this all, for the cerebellum, squashed down into the spinal canal, may too show signs of abrogation of function. The following case well exemplifies the occurrence of false localising signs, with long-standing pressure. A man aged 24 years came under observation totally blind from complete optic atrophy following papilloedema. He had had general symptoms of intracranial tumour for 18 months. He presented bilateral cerebellar signs, more marked on the right side, and right paralysis of the seventh nerve. He had had two Jacksonian attacks, commencing in the right arm. No history of any cerebellar symptoms could be gathered from the history of

the first year of his illness. Notwithstanding a warning, an operation for decompression of the subtentorial space was performed, with an immediately fatal result. An extradural tumour was found in front of the tip of the right temporal lobe. In this case, all the late developing signs were of false localising value.

Diagnosis.—The differential diagnosis of intracranial tumour has to be made—(1) from other conditions causing papilloedema, (2) from other conditions causing headache, and (3) from other local lesions causing local signs within the brain. Renal disease, conditions of severe anæmia, encephalitis and meningitis may on occasion give rise to a combination of all three of these, very easily confused with the papilloedema, headache and vomiting of cerebral tumour.

Hydrocephalus is only distinguishable from intracranial tumour by the enlargement of the head which takes place in young subjects, but when the skull is rigidly closed, the symptoms are identical with those of a non-localisable tumour.

Intracranial abscess is not often confused with tumour, when it has an obvious cause in the vicinity of the brain, from bone disease, or an embolic cause at a distance, such as ulceration of the lung. It is an acute disease and rarely develops an increasing papilloedema. Accuracy in the early diagnosis of tumour cases depends upon the pertinacity with which every case of headache, every case of "fits" and indeed every case which shows any nervous symptom whatsoever, is systematically examined for signs of organic disease, and importantly upon that skill and practice with the ophthalmoscope which is so easily acquired with patience and a little determination. The presence of a tumour having been determined, the necessity is to localise it. This can be done with an accuracy which approaches certainty in recent cases of tumour situated anywhere below the tentorium, provided that the condition of the patient admits of adequate examination, and even in half-comatose patients accurate judgment may lead to brilliant success. For example, in a case recently in the National Hospital with intense papilloedema, the patient was seen for the first time more than semi-comatose and half-moribund, and not in a physiological condition for examination. Yet the extreme hypotonicity of his limbs on one side, as compared with the other, led to the immediate and successful removal of a tumour of the lateral lobe of the cerebellum.

Above the tentorium tumours may be difficult or impossible to localise. So far as decompression is concerned the least indication, however slight, should determine the position of decompression. The external surface of the head should be carefully examined, and especially after it has been shaved, for now and then important indications of the position of a tumour may be afforded, for tumours may grow from the bone, or when internal may cause local absorption of the bone, and bulging of the skull. X-ray examination should not be omitted, though it does not often afford important information.

The determination of the nature of a growth is one of great difficulty, except in metastatic growths, when the primary growth has been discovered. Even where the serum reactions for syphilis or definite tuberculosis are present, the nature of a growth must remain one of probability and not of certainty.

Especial care must be taken not to assign a growth to a syphilitic origin because the administration of mercury and iodides relieves or even removes

the symptoms. We have on five occasions performed autopsy upon such apparently cured cases, after an interval of from 1 to 2 years, and we found sarcoma twice, glioma twice and tuberculoma once.

Course and Prognosis.—An intracranial tumour usually causes increasing symptoms, which progress with exacerbations and remissions, until papilloedema ends in blindness, and until the pathological intracranial condition becomes incompatible with even vegetative existence. At any time death may occur from vascular lesions, acute oedema or sudden raising of pressure. Tumours occasionally become obsolete—thus a tuberculoma may become scarred and calcified, and a glioma may become calcified or cystic; but this result is too rare for consideration within the grounds of practical perspective. The average duration rarely exceeds a year after the diagnosis has become possible.

Treatment.—In every case, whatever be the nature of the tumour, the regular administration of mercury, preferably by inunction, and of iodide of potassium is likely to lessen the severity and to slow down the course of the symptoms, and it should be used as an initial palliative measure in every case after the blood and cerebro-spinal fluids have been examined for syphilitic reactions. In syphilitic cases a cure may be effected, but such a cure occurs as a rule only in cases of syphilitic hydrocephalus from adhesive meningitis, which have simulated tumour. Massive cerebral gummata are not easily removed by treatment, and some of them are so hard as to be practically uninfluenced by anti-syphilitic treatment. Pain and vomiting may be relieved admirably with the various analgesics of the coal-tar series. When intracranial pressure becomes so high as to cause agonising pain, pulselessness and impending death, morphine in full doses will always relieve, and it is not dangerous. Convulsions should be combated with administration of bromides. The painful, dangerous and incapacitating symptoms of cerebral tumour—pain, sudden death, blindness and increasing torpor—result from increased pressure upon the brain; and if that pressure can be safely relieved, pain disappears for good and all, the sight is saved, and mental torpor is much lessened. This relief can be obtained by the operation of decompression, which by removal of the bone of the skull widely over the site of the growth, and the severance of the hard membranes, allows the tumour to bulge and grow outwards beneath the scalp, and frees the brain permanently from pressure. This operation should be undertaken in every case where localisation is certain, and where the tumour is in such a position that decompression will give relief, as a palliative measure to relieve headache and to prevent blindness, and it should be performed before the papilloedema has put the patient within any risk of blindness. If, by good fortune, a removable tumour is found at the operation for decompression, and can be removed without too much damage to brain and vessels, the operation becomes a radical curative one. Decompression is inadmissible in tumours of the brain stem, for it does no good, and when secondary hydrocephalus is associated, it is highly dangerous. When no localisation can be made, and the general symptoms are very urgent, decompression should be made far back and upon the right side over the hemisphere. It is made on the right side to avoid injury of the left convexity producing aphasia, and far back to avoid hemiplegia. It is by no means a light matter to decompress far away from the situation of the tumour, since the tumour will tend to shift

and grow towards the opening in the skull and produce disastrous effects in the way of tissue dislocation, vascular lesions and œdema; but where no localisation can be made, these results must be risked in the attempt to relieve the symptoms. Decompression is fraught with considerable danger to life, which becomes much greater the longer it is delayed. In decompression below the tentorium, the bone is removed both above and below the line of the lateral sinus, so that if hydrocephalus be present, as is so often the case, the supratentorial pressure can be relieved at any moment by tapping the lateral ventricle through the occipital lobe. The margin of the foramen magnum is cut away, so as to obviate the blocking effects of the pressure cone.

No attempt must be made to remove a tuberculoma which is found on decompression, however favourably it may be situated for removal, since any disturbance of its seat results invariably in tuberculous meningitis and death. On the other hand, tuberculous tumours not unfrequently become obsolete after decompression.

HYDROCEPHALUS

Definition.—The term “hydrocephalus” denotes a regular distension of the ventricular system of the brain by the accumulation of cerebro-spinal fluid within it; and this distension is associated, sooner or later, with an expansion of the cranial bones and enlargement of the skull.

Hydrocephalus was formerly divided into acute and chronic, acute being applied to the condition of tuberculous meningitis. But since any marked degree of ventricular distension is unusual in that affection, and enlargement of the head very rarely occurs, this term has fallen out of use. In the majority of cases in which general atrophy of the cerebral tissues occurs, fluid accumulates both in the ventricles and in the sub-arachnoid space; but such compensatory enlargement is not to be regarded as, in any sense, of the same nature as true hydrocephalus. Such accumulation of fluid is found in cases of cerebral diplegia and general paralysis of the insane in children, and it also occurs in the brains of old people. It is merely the result of wasting and shrinkage of the brain-tissue, and the accumulation of fluid takes place in order to fill up the space which is vacated within the rigid skull.

The enlargement of the head, which is not uncommonly found in rickets, has no connection with hydrocephalus. It is probably the result of malnutrition of cranial bones, which grow irregularly, and, being unduly soft, yield somewhat to the intracranial pressure. In rare cases of moderate degree, ventricular distension has been met with, but the enlargement of the head is never progressive, and the symptoms of hydrocephalus are absent.

According to their clinical aspect, cases of hydrocephalus may be placed in one of three groups—(1) congenital hydrocephalus, in which the enlargement of the head is present at the time of birth; (2) acquired primary hydrocephalus, which may appear at any period of life; and (3) secondary hydrocephalus. Under the name of secondary hydrocephalus may be grouped together all cases in which there is obstruction in the usual path by which the cerebro-spinal fluid leaves the ventricular cavities, or to the

venous outflow from the choroid plexuses. But it is by no means clear that such obstruction is the sole or even the important agent in producing the ventricular distension.

Ætiology.—Hereditary influences are of importance in the causation of congenital hydrocephalus. This disease frequently affects several children of the same parents, and it may even appear as a striking family disease, affecting members of several generations of the same stock. The writers have on two occasions seen hydrocephalic twins. *Spina bifida*, *meningocele* and *hydromyelia* are of frequent occurrence in association with this disease, and arrested and irregular development of the brain stem and cerebellum are the rule. Among other bodily deformities not infrequently associated with congenital hydrocephalus, may be mentioned *harelip*, *cleft palate*, *talipes*, *rectal and testicular ectopia* and *imperforate anus*. *Consanguinity of parents* and *parental alcoholism* have been recorded, and *syphilis* seems to have a definite connection with certain cases of congenital hydrocephalus. In the majority of syphilitic cases, the morbid anatomy of the hydrocephalus presents no special feature. In a few cases definitely syphilitic lesions of the *ependyma* in the region of the brain stem have been found. The causation of primary hydrocephalus occurring after the time of birth is often obscure. The majority of the cases occur in childhood, yet no period of life seems to be exempt. History relates that Dean Swift died of this malady at the age of 70, after having suffered from symptoms for 3 years. In children, acute infective diseases, and especially *gastro-intestinal infections*, may occur as antecedents of hydrocephalus. In adults, syphilis stands in important relation in certain cases, some of which have been examined pathologically. In 3 of such cases there was evidence of old syphilitic disease of the brain, but no obstructive lesion by which ventricular distension could have arisen mechanically. A history of *traumatism*, such as a severe blow or fall upon the head, a short time prior to the onset of the symptoms, is obtained so frequently as to have led to the description by certain authors of *traumatic hydrocephalus* as a special variety. There seems to be little doubt that injury may be the immediate cause of the appearance of symptoms, and that it is not always merely coincidental.

The causes of *secondary hydrocephalus* are, first, the *sclerosing forms of meningitis*, especially *posterior basic* and *epidemic meningitis*, very rarely *tubercular*; secondly, *intracranial neoplasms* encroaching upon the ventricular system, especially *tumours of the brain-stem* and *subtentorial region*; thirdly, *adhesive phlebitis of the cerebral blood-sinuses*.

Pathology.—Hydrocephalus is immediately due to an excess of cerebro-spinal fluid present in the cavity of the central nervous system. Such accumulation may result from the over-production of cerebro-spinal fluid by the epithelial lining of the nervous canal, or from an obstruction of those paths by which the fluid leaves the ventricles to enter the arachnoid space, or of the channels by which the fluid returns to the blood stream. Our knowledge concerning the origin and fate of the cerebro-spinal fluid, and of the manner in which it circulates, is at the present time far from complete. It appears to be secreted by the ependymal lining of the nervous canal, especially by that portion overlying the choroid plexuses of the ventricles. In some cases of cerebral tumour, a part of the lateral ventricles may be completely cut off by the growth from the general ventricular cavities, gener-

ally the tip of either the anterior or posterior cornu; and in such circumstances the isolated portion of the ventricle does not necessarily become distended. This fact would suggest that the cerebro-spinal fluid is chiefly secreted in the region of the choroid plexus. There are three pairs of choroid plexuses, situated respectively in the floor of the lateral ventricles, hanging from the roof of the third ventricle, and in the roof of the fourth ventricle. Cerebro-spinal fluid secreted in these regions is supposed to leave the nervous canal and enter the arachnoid space by certain apertures where these spaces communicate. Such communications exist in the region of the anterior perforated spots, in the region of the posterior perforated spot, and, lastly, in the thin roof of the fourth ventricle. The latter are comparatively large apertures, and are three in number, one being situated dorsal to the opening of the central canal of the spinal cord (foramen of Majendie), and the other two are placed one over each lateral recess of the fourth ventricle (foramina of Luschka).

Entering the subdural space, the fluid is absorbed by the vessels of the Pacchionian bodies and by the vessels of the meninges generally.

There are certain strong arguments that much of the cerebro-spinal fluid is absorbed in the lower part of the theca spinalis. Further, it is the rule in human subjects, where blood has escaped into the subdural space of the cranium as the result of injury or operation, to find blood clots around the nerves of the cauda equina, when opportunity is afforded for examining such cases at an early period after the extravasation has occurred. A further argument in support of the stream of cerebro-spinal fluid from brain-case to theca is that in certain cases of cerebral tumour, as a result of general pressure, the cerebellum and medulla become pushed down and plug the foramen magnum. Distension of the ventricle and urgent symptoms immediately follow, while no cause for such distension, other than filling up the foramen magnum, is discernible.

The quantity of cerebro-spinal fluid present in the normal human subject is quite small, probably less than 6 ounces. It comes and goes as the volume of the central nervous organs expands and contracts under the influence of the blood-pressure and of the relative calibre of the cerebral vessels. In so doing, the intracranial pressure is kept almost constant. When the subdural space is opened, the amount of cerebro-spinal fluid which may escape in the course of 24 hours is great, amounting in some cases to several gallons. It is improbable that secretion takes place as rapidly in the intact subject, and it may be that the copious draining of the fluid, when the dura mater is opened, is simply the expression of the natural mechanism for raising the lowered intracranial pressure to the normal.

According to the results of the investigation of the central nervous organs, cases of hydrocephalus fall into two groups. In one, the ventricular distension is the result of a known antecedent morbid condition, either meningitis or some form of intracranial growth, and the mechanism of its production, in part at least, is the obliteration of the usual paths of flow of the cerebro-spinal fluid. In addition, strangling of the veins collecting blood from the choroid plexuses may cause congestion and consequent transudation. The second group comprises those cases in which the hydrocephalus is apparently idiopathic, the veins and the outlets of the cerebro-spinal fluid being free. There is always some departure from the normal to be found in the structure

of the ependymal lining of the ventricle, and sometimes the change is very marked. Meningitis is apt to be followed by hydrocephalus in proportion as recovery from the initial disease occurs, in proportion as cicatrisation follows the inflammatory process, and in proportion as the affection of the covering of the fourth ventricle tends to cause obliteration of the foramina of Magendie and Luschka; and, further, in proportion to the amount of ependymal cicatrisation that may result. When blocking of the posterior foramina occurs, the only path of exit for the cerebro-spinal fluid is by the fine canals in the perforated spots. These, when patent, appear to be inadequate to prevent a relative increase of intraventricular pressure, for they are frequently found so enlarged in cases of hydrocephalus as to admit a fine probe. More frequently, however, they too are easily sealed by the inflammatory process, and a gradually increasing general ventricular distension thus results.

Not infrequently the vascular supply of the large choroid plexuses of the lateral and third ventricles is interfered with by cicatrisation following inflammatory processes which, spreading between the cerebrum and cerebellum, have extended to that double fold of pia arachnoid which extends into the great transverse fissure of the brain and separates the lateral and third ventricles, the *velum interpositum*. This membrane carries the great choroid plexuses, those of the lateral ventricle upon its upper surface, and those for the third ventricle upon its under surface, and lying between its folds are the veins of Galen which convey the blood from these plexuses to the straight sinus. Cicatrisation of the *velum interpositum* of necessity hinders the blood flow in the veins of Galen, and there being no anastomosis with the superficial cerebral veins, the result is an increased production of fluid by the congested choroid plexuses. In the hydrocephalus following meningitis the phenomena above described often coexist. It will follow from the above statements, that hydrocephalus is not a sequel of the more acute and rapidly fatal forms of meningitis, but of the more chronic and indurated forms, when these affect the posterior fossa of the skull, namely, epidemic meningitis, posterior basic meningitis and syphilitic meningitis.

Tumours of the brain cause hydrocephalus in the majority of cases by simple mechanical obstruction of the channel of exit of the cerebro-spinal fluid. The growth is usually situated in the mid-brain or pons, and, either by pressure or actual involvement, occludes the Sylvian aqueduct. Less commonly, pressure upon the brain stem from a growth in the immediate neighbourhood may cause the same result—for example, a tumour of the fifth nerve pressing upon the pons. Tumours which are firm and those which grow rapidly are more liable to obstruct the aqueduct than those which are soft or which grow slowly. It may be remarked in this place that in the majority of cases of cerebral tumour of long standing some dilatation of the ventricles is found post mortem, yet the growth neither involves nor presses upon the aqueduct, but may be situated in the frontal or temporal lobe, or may even be extra-medullary and growing from the skull in the anterior fossa. The degree of distension is usually not great, and it involves all the ventricles. Sometimes, however, the distension is extreme and the outward manifestations of hydrocephalus are present.

The quantity of fluid which is found in the ventricles after death varies greatly, a usual quantity being from 15 to 20 ounces. In long-standing

cases with great cranial enlargement, very large quantities have been met with, and in one instance recorded by Esquirol as much as 720 ounces were found. The characters of the fluid do not differ greatly from those of normal cerebro-spinal fluid. Its density varies from 1008 to 1010. It is clear, colourless or slightly yellowish, and the reaction is alkaline. It contains a very small quantity of albumin and a comparatively large quantity of alkaline chlorides.

The dilatation of the lateral ventricles is always more extensive than that of the third ventricle, and is usually symmetrical upon the two sides, and it affects the body of the ventricle more than the cornua, so that the central cortex is the most thinned. Sometimes one lateral ventricle is much more dilated than the other, and one of the horns may present extensive enlargement while the others are less affected, no cause being apparent for this irregularity, such as occlusion of any of the interventricular passages. The foramina of Monro are greatly enlarged and the anterior pillars wasted. The anatomical limitations and markings which are normally seen upon the walls of the ventricles become less obvious and often unrecognisable.

The ependyma is sometimes thickened, generally shining, and the network of subependymal vessels stands out obviously. The choroid plexuses are hypertrophied and thickened in less acute cases, but they may be found small, flattened and bloodless in acute cases. The dilatation of the ventricles occurs chiefly at the expense of the white substance of the hemisphere, the cortex and central ganglia being less affected. The convolutions are flattened, and the sulci indistinct or unrecognisable, according to the degree of distension. The thickness of the cerebral substance is much reduced, and especially in the region of the central convolutions, where in severe cases it may measure a few centimetres only. The corpus callosum is greatly wasted. In advanced cases, the cerebral hemispheres have the appearance of a thin-walled sac, which collapses entirely when the contained fluid is allowed to escape. The aqueduct of Sylvius may be much dilated, and when this is the case, the fourth ventricle shares in the general ventricular distension, the cavum cerebelli being especially enlarged. In many cases, however, the aqueduct and the fourth ventricle are not markedly distended. In a few cases, the aqueduct has been found closed, as if by antecedent adhesive ependymitis. The posterior part of the cerebellum and the medulla are passed down as a plug into the foramen magnum, and there is constantly a well-marked constriction in the posterior inferior part of the cerebellum, caused by the pressure of the bony ring of the foramen magnum. The theca spinalis and its processes into the intervertebral foramina may be much distended.

The condition of the pial roof of the fourth ventricle is of great importance, considering the widely-held opinion that hydrocephalus is of obstructive origin. In congenital and in primary hydrocephalus there may be some thickening of the ependyma, both of the roof and of the floor of the fourth ventricle, but there is no blocking of the posterior foramina. Where hydrocephalus is secondary to the presence of intracranial tumour, the growth may be situated in any position, either above or below the tentorium, and is not necessarily in such a position as to cause direct obstruction to the flow of the cerebro-spinal fluid. Sometimes, the lateral ventricle may be completely divided by a growth, and then the isolated portion of the ventricles

is sometimes found distended, and sometimes empty. Tumours, which directly or indirectly block the foramen of Monro and the aqueduct of Sylvius, are almost invariably associated with hydrocephalus, and of these glioma of the pons is the most frequent.

When hydrocephalus is secondary to meningitis, there is usually much meningeal cicatrisation about the roof of the fourth ventricle at the anterior and posterior perforated spots, and about the edge of the tentorium, where the veins of Galen enter the straight sinus, and extend forwards along these veins in the velum interpositum. The ependyma is usually thickened and shows evidence of past ependymitis.

Symptoms.—The clinical manifestations of hydrocephalus fall into two groups, which result, respectively, from the effects of the abnormal intracranial pressure, first upon the brain-case, and secondly upon the nervous structures. In the congenital form, the enlargement of the head is the first noticeable feature; and this is true also of some cases of acquired hydrocephalus in young children. In most cases of acquired hydrocephalus, on the other hand, the nervous symptoms are first in evidence—namely, persistent headache, vomiting, mental impairment, convulsions and sometimes papilloedema. The evidence of cranial enlargement may succeed these symptoms, and the older the subject, and consequently the more resistant the cranial walls, the more severe are the nervous symptoms, and the later is the cranial enlargement in appearing. In some cases of congenital hydrocephalus, enlargement of the head takes place during intra-uterine life, and it may be so great as to make delivery impossible without destruction of the head. More frequently, the cranial enlargement, not noted at the time of birth, becomes evident during the first few weeks of life.

Enlargement of the head is the most striking feature of hydrocephalus in children. The increase usually affects all the diameters of the cranial cavity, and is most marked on the vertex and least at the base. Trousseau compared the opening out of the cranial bones, which occurs as the head enlarges, to falling back of the petals of an opening flower. The forehead is large, rounded, and projects forwards; the temporal fossæ are obliterated, and the parietal eminences carried backwards. The vertex is often somewhat flattened, as also may be the occipital region. The direction of the external auditory meatus alters with the increasing size of the head; normally directed obliquely forwards, it comes to look directly inwards, or even obliquely backwards in severe cases. The head is frequently asymmetrical. In young children the sutures may be widely open, and then there is marked bulging along those lines and at the fontanelles. The skull may attain enormous dimensions, and many examples are recorded in which the circumference has been from 60 to 90 cm. The face is characteristically triangular, contrasting markedly with the forehead. Wasting of the facial subcutaneous tissues and retarded development of the maxilla and mandible often render this contrast still more striking. Bulging of the orbital plates of the frontal bone presses down the eyeballs, so that the pupils become more or less covered by the lower lids, and a band of the sclerotic may be visible between the iris and the upper lid. The hydrocephalic child often uses his hands to depress the cheeks, and so draw down the lower lids out of the position in which they impair the line of vision. The hair of the head becomes scanty, the subcutaneous veins of the scalp are often greatly developed and distended,

and sometimes a vortex of distended veins radiates from the region of the anterior fontanelle. The general nutrition is poor, and bodily development retarded, in proportion to the severity of the effect of the intracranial pressure upon the nervous system. Auscultation may reveal a cephalic bruit, but this is neither a characteristic nor a constant sign in hydrocephalus, for it is frequently met with in rickety children, and may be present in a normal subject.

The nervous disorders which appear during the course of hydrocephalus are both variable and inconstant, and acute symptoms are of rare occurrence, if the disease appears at an age at which the skull is still yielding. On the other hand, if the ventricular distension commences when the growth and ossification of the skull are complete, the nervous symptoms which arise are very severe, and resemble closely the general effects of intracranial growths. In secondary hydrocephalus, the symptoms due to this condition emerge from those of the preceding meningitis or sinus thrombosis, or are blended with those of the coexisting intracranial growth.

In children, the nervous symptoms of hydrocephalus, whether it be congenital or acquired, may be summed up in the following list, the symptoms being frequent in the order in which they are enumerated: convulsion, mental failure, spastic paralysis of the limbs, headache, optic atrophy, nystagmus, vomiting, papilloedema. There is no constancy in the occurrence of these symptoms. Convulsion may not occur at all, and mental acuity may be unimpaired. Spastic weakness occurs in less than one-half of the cases, whilst optic atrophy is met with still more rarely, and papilloedema is distinctly unusual.

Convulsion.—While it is to be borne in mind that the whole course of hydrocephalus in children may run without the occurrence of convulsion, yet in the majority of cases this symptom is conspicuous. In some of the post-natal cases the symptoms of cerebral disorder are ushered in by convulsion, and it is probable that such convulsions are the immediate expressions of the morbid process, of which the primary hydrocephalus is the final result. The convulsions which recur at intervals throughout the course of the majority of cases of hydrocephalus result from a condition of functional instability of the cerebral cortex, which long-continued increased intracranial pressure brings about. The convulsions are usually general, with loss of consciousness. A preceding aura is rare. Local commencement of the spasm, which becomes general, associated with loss of consciousness, is not infrequently observed. Local convulsion without loss of consciousness (Jacksonian epilepsy) may occur repeatedly in some cases, and may lead to the erroneous diagnosis of a gross local lesion in the cerebral cortex, and especially is this error likely to occur when hydrocephalus is secondary to intracranial tumour.

The explanation of the occurrence of such local convulsion is that the effect of the pressure is not equally distributed upon the cortex,—the central region tends to suffer earlier and in greater degree than do other regions,—and that some *locus minoris resistentiæ* loses its functional stability earlier and in greater degree than does the rest of the cortex. All degrees of mental reduction occur, from the least noticeable to complete idiocy. The more severe forms of mental impairment are met with in congenital cases, and especially when cerebral agenesis, porencephaly and teratological defects are associated. The psychical reduction is less prominent the greater the age

at which the symptoms commence, and, as a rule, the intelligence is far greater than the severity of symptoms (cranial enlargement, paresis, etc.) might lead one to expect. Cerebration is usually slow and the disposition placid, and periods of somnolence are of common occurrence.

The effect of long-continued ventricular distension in many cases is to cause degeneration of the pyramidal system, and, according to its degree, the latter entails bilateral spastic paralysis with contracture. The first signs of the onset of this event are exaggeration of the deep reflexes, and the change in type of the plantar reflexes from the flexor to the extensor response. The lower extremities are affected earlier and to a greater extent than are the upper, and at one period of the disease a case may present the picture of cerebral paraplegic rigidity comparable with that of Little's disease. The upper extremities are affected later. The paresis of the limbs is almost always symmetrical and equal upon the two sides. Sensibility is generally normal.

Vision is interfered with in a considerable proportion of the cases. The enlargement of the infundibular portion of the third ventricle, by pressure upon the inner borders of the converging optic tracts, may cause bitemporal hemianopia with atrophy of the nasal portions of both optic disks, this condition subsequently progressing to complete blindness and complete optic atrophy. More often the increased intracranial pressure causes atrophy of the optic tracts and secondary atrophy of the optic disks.

In other cases, optic atrophy is the result of papilloedema. In late childhood and in adult life papilloedema is the rule, and optic atrophy seems always to be consecutive to this. Strabismus is commonly present in congenital cases, and it is most frequently convergent. Nystagmus is met with in the subjects of hydrocephalus who are blind from optic atrophy, and it is of frequent occurrence in long-standing cases in which spastic paresis is well-marked. In the latter case, it is probably a spastic ocular manifestation indicative of the degeneration of the cortical motor neurons subserving eye movements, and it is a feature of the same order as is spastic paresis in the limbs and trunk.

Headache is often complained of, and especially during the early days of illness in acquired cases, but this symptom never dominates the clinical picture in children, and is never so severe and persistent as that arising from the presence of an intracranial growth. Cerebral vomiting is of comparatively rare occurrence.

When one considers the profound anatomical alterations which take place in the advanced stages of the disease, the occurrence in some cases of unusual symptoms indicative of interference with the functions of the cerebellum, brain stem and cranial nerves is easily explicable. Unilateral or bilateral ataxy, vertigo, deafness, anosmia and paralysis of cranial nerves, are the most important of such unusual symptoms.

The signs of failure of the nervous system as a whole usher in the fatal result in severe cases. For some days or perhaps weeks before death, hebetude may become profound; spastic paresis gives place to flaccid paralysis with muscular wasting, the deep reflexes disappear, and the sphincter mechanism loses its control and subsequently its tone.

Hydrocephalus which commences in late childhood or in adult life presents an aspect widely different from that just described. At these periods of life,

the bones of the skull are firm and resistant, and the sutures resist for a long time before yielding to the increased intracranial pressure. The general symptoms are acute, and the course of the disease is often rapid to a fatal termination. There is usually no enlargement of the head to aid the diagnosis, and the symptoms—headache, vomiting and papilloedema—resemble those of a non-localisable intracranial growth.

The headache is severe and usually paroxysmal, and it may be so intense as to cause sudden death, while, not infrequently, the sufferer loses all control during the paroxysms. Speaking generally, the headache is of much greater severity in adult hydrocephalus than in intracranial growth. Similarly, vomiting is apt to be more severe and persistent than that associated with cerebral growth. In many of the cases, a fatal result occurs before enlargement of the head, and before cerebral degeneration has produced further signs of spastic paresis than an increase of the deep reflexes, foot clonus and the change of the plantar reflexes to the extensor type. General convulsions and attacks of coma are not rare.

Diagnosis.—Where enlargement of the head is manifest the diagnosis of the disease presents no difficulties. The large head of rickets is easily distinguishable from hydrocephalus by its different conformation, by the association of the other signs of rickets, by the absence of nervous symptoms, by its non-progressive nature, and by the results of anti-rachitic treatment. The distinction between the primary and the secondary forms of hydrocephalus in children should present no difficulty, if a correct history of the early symptoms can be obtained. The initial manifestations in the primary form are slight, and cannot be confused with those of meningitis or of sinus thrombosis. Intracranial growths which cause early and marked hydrocephalus are situated in some part of the brain-stem from the third ventricle to the medulla, and growth in such a position must of necessity produce such early pathognomonic localising signs as to leave no excuse for erroneous diagnosis, save imperfect observation.

The advent of ventricular distension in the course of intracranial growth is generally to be detected by the occurrence of widely spread bilateral signs such as bilateral spasticity, bilateral ataxy, general convulsion, and enlargement of the head. In the primary hydrocephalus of childhood, the disease is not distinguishable until the head begins to enlarge.

In adults the absence of cranial enlargement in most of the cases makes it impossible to separate the malady with certainty from intracranial growth. It must be borne in mind, however, that headache, vomiting and papilloedema of rapid progress are not necessarily signs of intracranial growth, but may be the symptoms of primary hydrocephalus.

Prognosis.—This depends upon the cause of the hydrocephalus, upon the degree of severity of the symptoms, and upon whether it is progressive or not. In all severe and progressive cases the prognosis is hopeless, and the same is true of hydrocephalus secondary to inoperable neoplasm. In some of the slighter cases, both of the congenital and of the acquired form, the process becomes arrested, and the patient may attain to adult life with the possession of all his faculties. In cases in which the disease becomes stationary, the prognosis as regards mental capacity and the continuance of recurring convulsion has to be considered. If the mental capacity at the time of arrest is fair, it is not likely to deteriorate further, unless epilepsy is

established. When mental reduction is marked at the time of arrest, a great degree of improvement cannot be reasonably expected.

Treatment.—While some cases of hydrocephalus cease to progress, and the symptoms disappear permanently under medical treatment, a like result has occurred in cases in which no treatment has been applied.

The importance of syphilis in the ætiology of hydrocephalus suggests the employment of anti-syphilitic treatment, and it is certain that the application of mercurial ointment to the head seems to do more good than any other measure, while the administration of iodide of potassium in full doses seems to benefit a few cases. The beneficial effect of the administration of mercury occurs not only in the syphilitic cases, but in all.

The results of surgical interference for the relief of pressure and to attempt the re-establishment of a way out for the cerebro-spinal fluid have been, up to the present, so unfavourable, that many writers and authorities consider such measures unjustifiable. It must be borne in mind, however, that in severe and progressive cases one is dealing with a necessarily fatal malady, and a few encouraging results have been published, which appear to justify further investigation. Paracentesis of the ventricle is both useless and dangerous, for when relief follows the operation it is only temporary, and where cerebral tension is very high an immediately fatal result may supervene. Repeated lumbar puncture is advisable in the earlier days; but this is only possible in cases in which the theca is in free communication with the ventricular space.

Various operations have been performed for the purpose of re-establishing communication between the ventricular and the sub-arachnoid space. The fourth ventricle has been drained and occlusion in its roof rendered patent, the trephine opening being made through the occipital bone; this operation has not been attended with successful results. An aperture has been made in the corpus callosum via the anterior fontanelle, with the object of establishing permanent communication between the lateral ventricle and the sub-arachnoid space. None of the many operative procedures which have been attempted for the relief of this malady have given particularly brilliant or uniform results, although there may have been occasional recoveries, even in advanced cases.

ENCEPHALITIS

ACUTE ENCEPHALITIS

Acute inflammation of the brain occurs under widely different clinical associations. It may occur as a primary disease or as a complication of known infective processes, affecting the system locally, generally, or as an associated event in diseases of the meninges. As a primary condition it is met with in the form of the Heine-Medin disease or poliomyelitis, and as lethargic encephalitis. It is the constant result of trauma to the skull, if this be sufficiently severe. It is found as the result of infection of the brain with pyogenic organisms, either from local sources in the neighbourhood of the brain (septic bone disease), or from pyæmia, and may be then either suppurative (brain abscess) or non-suppurative. Infections by many of the specific fevers may cause it, and especially measles and scarlet fever.

Acute encephalitis may occur in rare cases as the sole manifestation of cerebral syphilis. In all forms of meningitis there is some degree of extension of the inflammation into the brain tissue, and this assumes an important degree in tuberculous meningitis, and sometimes in epidemic meningitis. The symptoms common to all forms of encephalitis are the general symptoms of severe intracranial disease—headache, somnolence, coma, irritability, convulsions, delirium and vomiting; and, in addition, local symptoms of irritation and paralysis, which are determined by the position and extent of the lesions.

TRAUMATIC ENCEPHALITIS

As the result of a local blow upon the head or from the general concussion of sand-bagging or bursting of high explosives, the “commotio cerebialis” causes tissue disruption or bruising, which is immediately followed by hæmorrhage both on the surface and in the substances of the brain tissue, by œdema with much swelling, and by a general inflammatory reaction, which may go on to suppuration if a punctured wound or other event allows of the access of micro-organisms. The hæmorrhage and œdema, and particularly the œdema, are the causes, on the one hand, of the deepening local symptoms which are often observed after injuries to the head, and on the other hand, of the increasing general signs of cerebral loss of function, such as increasing coma and failure of respiration. The local raising of tissue tension in the region of the local injury tends to evascularise the region of the lesion, and increase the permanency of the damage. The general raising of the intracranial pressure results from the swelling and hæmorrhage. The important indications to which these considerations point, are that the chief danger of death and an important cause of persistence of local symptoms is a raised intracranial pressure, and that in every case where local or general symptoms are severe and increasing, craniectomy should be performed for its relief. This is the more important because, in such cases, the presence of hæmorrhage gradually accumulating between the dura and the bone from rupture of a meningeal vessel can never be excluded, and because intracerebral and meningeal hæmorrhages can be drained, or the resulting clot removed. The lumbar puncture in these cases shows a bloodstained fluid. It is remarkable how little “commotio cerebialis” may result from the passage of a high velocity bullet through the brain and skull.

SUPPURATIVE ENCEPHALITIS (INTRACRANIAL ABSCESS)

Ætiology.—Suppuration within the brain substance is never primary, but the result of extension of infection from neighbouring tissues or by the blood stream from foci of infection in distant organs. In rare cases, the focus of original infection is undiscoverable.

The following are the important causal factors :

1. **Trauma.**—In the case of penetrating wounds the missile may be the source of the infection. Lacerated wound with fracture may allow of infection from the surface or from the middle ear, nose or pharynx. In these cases, meningitis often occurs in addition to abscess. Though not traumatic in a strict sense, any local lesion of the brain may become a *locus resistentiæ minoris* for the settling down of suppurative organisms derived

from the blood stream, and in this way abscess has followed upon vascular lesions and the lesions of primary encephalitis.

2. *Extension from infected regions* in the immediate vicinity. The important cause of infection is any form of infective disease in the bones or soft tissues of the skull, calvarium and surrounding regions. Caries of the petrous bone from middle ear disease is the most common cause, while septic conditions of the nasal cavities and their accessory sinuses, or of any of the bones of the skull, suppuration of the scalp, orbital cellulitis and carbuncle of the neck are other causes. The exact manner of advent of the infection into the brain substance may differ in different cases. It may be by a septic thrombosis of a vein communicating between the infected region and the brain, or by extension along lymphatics similarly communicating, or by direct extension, as when the temporal lobe becomes adherent to the tegmen tympani, or it may be trans-meningeal by the direct transference of organisms across the meningeal space, without general meningitis occurring. That this latter mode of infection is a common one is suggested by the facts, that when the primary disease affects the upper surface of the petrous bone, the abscess is in the temporal lobe, and when the posterior aspect of the temporal bone is affected the abscess is in the cerebellum; and, most importantly, in all these cases of abscess from extension, the cerebrospinal fluid shows the presence of polymorphonuclear leucocytes, thus showing that the meninges have been infected, although no symptoms of meningitis arise.

3. *Pyæmic states*.—Abscess of the brain does not often occur in symptomatic pyæmia. It may occur in infective endocarditis, and then multiple abscesses may be found. Sometimes in this condition multiple small spots of encephalitis, containing many polymorphonuclear cells but not definite abscesses, are met with. Much more commonly, abscess results from a single septic embolus from chronic pulmonary infection, such as bronchiectasis, empyema and lung abscess. In rare cases metastatic abscess may arise from bone disease, liver abscess and in the course of specific fevers. The micro-organisms responsible for the infection are usually streptococcus, pneumococcus and staphylococcus, and often the infection is mixed. *B. coli* is sometimes found, and in rare cases streptothrix and *oidium albicans*.

Pathology.—The abscesses which result from local disease of the skull bones and surrounding tissues may be extradural, subdural or encephalic: in the first two cases they are invariably situated in the immediate vicinity of the antecedent seat of infection. The extradural abscess may reach a very considerable size and may burst externally, or into the meninges or into a blood sinus. The subdural abscess is confined in meningeal adhesions between the dura mater and pia mater. The contiguous surface of the brain is generally softened and has often disappeared, the abscess cavity extending deeply into the brain substance. This variety rarely has any capsule on the cerebral side. Encephalic abscess commences generally in the subsulcine white matter of the temporal lobe, and lateral lobe of the cerebellum. In one-half of all cases the abscess is in the temporal lobe, and in one-third in the lateral lobe of the cerebellum. The remainder are divided between the parietal lobe, the pons Varolii and the frontal lobe, in order of diminishing frequency. The size of the abscess varies up to that of a hen's egg. A recently formed abscess is irregular in shape with ill-defined limits, but in

about 7 days it shows a definite capsule which may rapidly become of considerable thickness. The interior of the abscess cavity is usually of a greyish-green colour, and the pus is greenish and often foetid. The surrounding brain tissue is always oedematous and often softened. Rupture occurs in about one-sixth of all cases that are not afforded operative interference, and the rupture takes place most commonly into the ventricle and less frequently into the arachnoid space.

Symptoms.—An encephalic abscess has its origin in inflammation, and constitutes, when developed, a foreign body within the skull. Death may result from the effects of continually increasing intracranial pressure and wide interference with cerebral function, or from spread of the infection from the abscess. The symptoms may be grouped in four classes—(1) those of local suppuration; (2) those due to increased intracranial pressure; (3) localising signs dependent upon the position of the abscess; and (4) those of terminal extension of the infective process.

In extradural and subdural cases, the symptoms are generally acute and the course is rapid; the signs of pressure are severe, whilst localising signs are rare and a state of latency is not observed. In the majority of encephalic abscesses, on the contrary, the signs of initial suppuration are slight and are apt to be swamped by the symptoms of the preceding disease, otitis media, empyema, infective endocarditis, etc., and for this reason may be easily overlooked. A latent period in which symptoms are insignificant or completely absent may follow, and last for weeks or months. In the end, the latent period is broken, either by an acute outburst of symptoms, the result of extending infection, or the signs of progressive intracranial tumour arise.

The general symptoms which are likely to appear when a brain abscess is developing or emerging from a latent condition are pyrexia, which may be associated with rigor, headache, vomiting, irritability, vertigo, drowsiness deepening into coma, slowing of the pulse, respiratory and cardiac irregularity, convulsions rarely, and papilloedema as a late sign. In addition, there is a leucocytosis of the polymorphonuclear variety in the blood, and a small number of polymorphonuclear leucocytes in the cerebro-spinal fluid in those cases arising by extension from disease of the cranial bones, but not in metastatic abscesses. The general symptoms vary much in their intensity and in the individual incidence of each of them, and in metastatic abscesses they may be almost absent, the local signs alone giving the indication that a cerebral lesion is present. Headache is rarely absent, and may be intense with spreading abscess. Vomiting is also an almost constant sign. Drowsiness is one of the most valuable of all the indications when any cause for the occurrence of cerebral abscess is present. Slowing of the pulse is also an important indication of a rising intracranial pressure. Papilloedema occurs late, and is often not present in acute abscesses at the time when diagnosis is all-important from a surgical point of view. It rarely occurs until an abscess has been present for a week, and is generally of low grade. With half-latent chronic abscesses, and with metastatic abscesses which attain a large size, it may be intense.

Local signs.—Generally speaking, the more recent and acute the abscess is the less definite are the local signs. In more chronic abscess, and in metastatic abscess, the local signs are usually more distinct. When there is a

local cause for the abscess this constitutes an important localising sign, since abscess forms almost always in the immediate vicinity of site of infection. Thus rhinogenic abscesses are situated in the frontal region, and otitic abscesses are almost invariably situated either in the temporal lobe or in the lateral lobe of the cerebellum of the same side as the ear disease.

Metastatic brain abscesses may be situated anywhere, but they are more common in the region of distribution of the Sylvian artery, and in my experience have been more common in the posterior part of this supply—that is, in the parietal and occipital lobes. Metastatic abscess is sometimes preceded by definite indications of the embolism which gives rise to the abscess, such as local convulsion, local transient weakness or loss of consciousness, and such an event may precede the signs of abscess by many weeks. The local signs of lesion in the various regions of the brain are described in the section under that heading. Local diagnosis is often difficult owing to the condition of somnolence preventing the possibility of accurate examination. In these circumstances such slight signs as the absence of the abdominal reflex on one side, the presence of an extensor response in the plantar reflex of one side, or any aphasic signs, are important indications of temporal lesions, and unilateral hypotonia and nystagmus and attitudes of cerebellar lesions. The initial signs and symptoms of encephalic abscess may lessen and disappear, and the abscess is said to become latent. The latency may be complete, or it may be broken by occasional headaches and transitory symptoms indicative of intracranial mischief. Much more commonly the abscess grows, and death occurs invariably in the absence of surgical interference, either from increasing intracranial pressure or from the rupture of the abscess, either into the ventricle, or on to the surface, with the production of general meningitis.

Diagnosis.—In those cases where there is no local cause for the formation of an intracranial abscess by direct extension, and no distant cause known or discoverable for the formation of a metastatic abscess, diagnosis is difficult, and the distinction of an abscess from a tumour can hardly be made with certainty. The presence of pyrexia and of a polymorphonuclear leucocytosis in the blood may suggest the diagnosis in some cases. Where however the common antecedent causes of abscess exist in the form of ear disease, etc., or suppurative chronic lung disease, the diagnosis is relatively simple. For example, the advent of local or general intracranial signs in a case of chronic bronchiectasis from the first leaves no alternative diagnosis. When ear disease or local septic conditions of the region of the skull are present, local and general intracranial signs are due either to meningitis, abscess, sinus thrombosis, osteomyelitis of the base of the skull, or rarely to acute otitis.

Meningitis can be at once distinguished not only on account of the more irritative and rapidly oncoming symptoms, which differ somewhat from those of abscess, such as head retraction and rigidity of the neck, Kernig's sign, delirium and tremors, but by the lumbar puncture which gives the turbid cerebro-spinal fluid, containing polymorphonuclear cells and organisms in quantity. It must not be lost sight of that an abscess at any stage of its formation may be complicated by the development of general suppurative meningitis. Sinus thrombosis is usually accompanied by much oscillation of temperature, and by repeated rigors and oedema, and tenderness in the

region of the emissary veins of the blocked sinus may be present. The diagnosis of the latter condition is not of vital importance, and its consideration should cause no delay in summoning the aid of the surgeon. The presence of any symptoms of intracranial disturbance, where tympanic septic disease exists, calls for immediate surgical interference, and the surgeon, after cleaning out the diseased tympanum, completes the diagnosis by examining the lateral sinus, both the temporal lobes and the lateral cerebellar hemisphere, and proceeds to those measures which the results of his exploration indicate. Acute otitis media may give rise to severe intracranial symptoms like those of meningitis, convulsions even occurring which may subside dramatically after perforation of the tympanic membrane, but it must be remembered that the chronic and not the acute forms of otitis give rise to septic extension to the brain. Osteomyelitis of the base of the skull extends from chronic bone disease in the region of the ear or nose. There is much pain in the base of the skull, and sometimes many cranial nerves are implicated at their foramina of exit. Skiagraphy will indicate the loss of bony structure. The malady is a chronic one, and usually ends in a terminal meningitis.

Prognosis.—Cerebral abscesses with very thick walls and inspissated or even calcified contents have been found post mortem, many years after the presumed time of formation of the abscess. Spontaneous evacuation of an abscess through the diseased ear, or through a sinus in the area of the local disease causing the abscess, has been followed by recovery. It is probable that no abscess becomes permanently quiescent after it has given rise to severe symptoms. The prognosis in cases of cerebral abscess, therefore, is that a fatal result will occur, unless successful surgical interference is possible. If the abscess is reached and drained, recovery often occurs rapidly, but this is never certain, for extensive perifocal softening, meningitis and sinus thrombosis may occur. Moreover, a general suppurative encephalitis may extend, in spite of draining the abscess.

Treatment.—The most rigorous prophylaxis should be employed that all patients suffering from septic nasal and ear diseases, and infective disease of the scalp and cranial bones, shall not pass out of observation until such disease is beyond all doubt cured. The only treatment for developed abscess is exploration and drainage. The liability to the occurrence of septic meningitis may perhaps be lessened by the administration of hexamine. The usual measures for the relief of pain should be employed.

ACUTE POLIOMYELITIS (see p. 134)

LETHARGIC ENCEPHALITIS (see p. 145)

MENINGITIS

EXAMINATION OF CEREBRO-SPINAL FLUID

In the last years of the nineteenth century, Quinke brought into prominence the examination of the cerebro-spinal fluid withdrawn by lumbar puncture as a means of diagnosis of diseases of the nervous system, and so great has the value of this examination proved, that it is now a routine

method of investigation in almost every variety of nervous disease. The cerebro-spinal fluid is the secretion of the meninges, and in almost every condition of pathological changes in the meninges or of the sublying tissue, or of the meningeal vessels, important information is to be gained from the examination of this fluid. A fitting introduction therefore to a consideration of diseases of the meninges is a description of the normal secretion of those membranes, of the changes which occur in pathological states and their significance, and of the method of examination and of withdrawal of the fluid.

The normal cerebro-spinal fluid is a clear colourless fluid which shows not the least trace of clot or flocculence on standing. It contains a minute trace of albumin which becomes no longer recognisable to the nitric-acid test, at dilutions of from 1 to 6, to 1 to 20. It also contains a trace of globulin, which disappears to the ammonium-sulphate test at dilution of 1 to 2. The normal glucose content is rather less than 0.1 per cent. There are normally a few lymphocytes not exceeding 6 per cubic millimetre. The lumbar puncture is made in the first interspinous space above a line joining the highest points of the iliac crests, which is the space between the third and fourth lumbar spines, or it may be made with equal rectitude in the space between the second and third lumbar spines. The needle should be introduced exactly in the middle line and at right angles to the surface, close to the upper spinous process of the interval used. Normally the fluid escapes drop by drop. If it runs rapidly or spurts out, this is an index of the increase of the cerebro-spinal pressure. Such an increase is met with in all meningeal inflammation, congestion and hæmorrhage, and in increased intracranial pressure.

INCREASE IN PROTEIN CONTENT.—This is of high importance, and occurs in all conditions of meningitis, and especially when the thecal space is obstructed by tumour, pressure from without, or meningeal adhesions. Normally the protein content is from 0.01 to 0.02 per cent. In pathological conditions it may reach 0.8 per cent. or more. A high protein content sometimes associated with xanthochromia, in the absence of cellular elements, is highly characteristic of thecal obstruction and is known as "Froin's syndrome." Lethargic encephalitis does not give any increase of protein.

All forms of polyneuritis (diphtherial excepted) are often accompanied by an increase of protein content.

Xanthochromia is a yellow colour of the cerebro-spinal fluid, and it is met with when the spinal canal is obstructed by tumours of the cord or meninges, or by external pressure. Occasionally the yellow colour may result from an old extravasation of blood either into the arachnoid or into the central nervous system bordering upon the arachnoid, and is then due to hæmatoidin.

Spontaneous coagulation of the fluid is met with in some cases of meningitis, when there is spinal obstruction, and in polyneuritis of any nature, except in diphtherial neuritis.

Blood may occur from the pricking of a small vessel in the lumbar puncture, and it renders the fluid useless for cytological examination. This bleeding usually ceases after a few cubic centimetres of the fluid have been withdrawn, and it is easily distinguishable by centrifugalisation from blood admixture due to pathological conditions, for in the latter case the supernatant fluid

after centrifugalisation is tinged yellow from hæmolyxis. Blood may occur from every condition of hæmorrhage, injury and encephalitis, and sometimes in meningitis. Blood that has been long shed into the cerebro-spinal fluid tends to become brownish and later yellowish. The red blood corpuscles are soon disintegrated in the fluid, but the white corpuscles persist. The leucocytosis thus resulting in the fluid can be at once distinguished from leucocytosis due to meningitis, etc., since the differential count is the same as that in the blood. Leucocytosis is indicative of meningitis and often occurs in encephalitis. A lymphocytosis is characteristic of tuberculous and syphilitic meningitis, poliomyelitis, lethargic encephalitis, sinus thrombosis and mumps. A polymorphonuclear cytolysis occurs in meningococcal meningitis and all the suppurative forms of meningitis. In tuberculous meningitis there is often a mixed cytolysis at first, in which the polymorphonuclear cells may form 60 per cent. of the total. In poliomyelitis, the lymphocytosis disappears after the end of a week. In lethargic encephalitis there is frequently no lymphocytosis.

Pus may be present in quantities in all the septic forms of meningitis, and especially in pneumococcal and epidemic meningitis. A turbid fluid is often met with in tuberculous and septic meningitis.

DECREASE IN GLUCOSE CONTENT.—All conditions of meningitis cause decrease in the glucose, for this disappears from an autolysis controlled by the leucocytic ferments and is converted into lactic acid.

LANGE'S COLLOIDAL GOLD REACTION.—Increasing dilutions of the cerebro-spinal fluid when mixed with colloidal gold and allowed to stand for twenty-four hours, exhibit varying colours according to the nature of the protein exudate, and this forms a test which is valuable in the diagnosis of syphilis and of disseminate sclerosis.

The nature of the organismal content is determined (1) by the direct examination of films made from the centrifugated fluid, (2) by cultures from the fluid, and (3) by the inoculation of animals from the fluid.

The Wassermann reaction in the fluid is positive in all conditions of recent syphilitic disease impinging upon the meninges, and always in general paralysis. Though often positive in tabes, it may be found negative. Lumbar puncture is dangerous in cases of long standing increased intracranial pressure, and if performed in such cases a minimum of fluid should be withdrawn. It may in some cases cause severe headache of long duration. It may be difficult or impossible to perform when there is bone disease of the lumbar vertebrae.

Definitions.—Inflammatory conditions affecting the membranes which cover the brain and spinal cord and which line the cerebral ventricles, may have their seat primarily in the dura mater (pachymeningitis), or in the pia arachnoid (leptomeningitis), or in the ependymal lining of the ventricles (ependymitis).

Ætiology.—Pachymeningitis is usually a local condition, and is often due to disease spreading into the dura from the contiguous bone. Leptomeningitis and ependymitis, from the facility with which microbic infection is spread in the cerebro-spinal space by the flow of the cerebro-spinal fluid, are not localised and the two conditions are often associated. The close relationship between the nervous tissue and its covering and lining membranes necessitate that leptomeningitis and ependymitis entail some degree

of encephalitis or myelitis by the extension of the inflammatory process into the sublying nervous tissue. With the exception of traumatic meningitis and possibly of serous meningitis, the various forms of meningitis are due to the infection of the cerebro-spinal space and its membranes by micro-organisms. This infection may arise secondarily to some well-marked infective lesion elsewhere within the body, or it may develop primarily.

CLASSIFICATION.—The most useful classification of the varieties of meningitis is according to the nature of the micro-organism producing the inflammation.

NAME.	ORGANISM.	CEREBRO-SPINAL FLUID.
Tuberculous meningitis .	Tubercle bacillus.	{ Clear or turbid. Lymphocytes, either alone or in greater numbers than polymorphs. Tubercle bacilli.
Pneumococcal meningitis .	Pneumococcus.	{ Turbid. Polymorpho-nuclear leucocytes. Pneumococci.
Meningococcal meningitis .		{ Clear or turbid.
Sporadic or posterior-basal.	Still's diplococcus.	{ Polymorpho-nuclear leucocytes.
Epidemic or "Spotted Fever."	Weichselbaum's diplococcus.	{ Intracellular diplococci.
Pyogenic meningitis .	{ Staphylococcus. Streptococcus. <i>B. influenzae</i> . Gonococcus. Streptothrix.	{ Turbid. Polymorpho-nuclear leucocytes. Or organisms.
Syphilitic meningitis .	<i>Spirochæta pallida</i> .	{ Clear. Lymphocytes only. Wassermann reaction. +.
Other forms	{ <i>B. typhosus</i> . <i>B. enteritidis</i> . }	Turbid. Polymorphs.
Rheumatic meningitis .	<i>Diplococcus rheumaticus</i> .	
Serous meningitis .		Clear. Few cells. Sterile.
Traumatic meningitis.		

TUBERCULOUS MENINGITIS

This disease results from the general invasion of the cerebro-spinal leptomeninges by the tubercle bacillus, and this organism invariably arrives in the meninges by the blood stream from some previously existing focus of tuberculous infection within the system, and most commonly from caseous glands and tuberculous bone disease. Occurring at all ages, it is the form by far the most frequently met with in the second and third years of life. The characteristic features of the cerebro-spinal fluid are, that it is usually under considerable pressure, it is clear or only slightly turbid, has no visible deposit before centrifugalisation, but it often forms a fine flocculent clot. It contains an excess of albumin. The normal sugar is generally absent. There is a pleocytosis with a high proportion of lymphocytes, 70 to 80 per cent. being of this nature, and the rest being polymorpho-nuclear. Careful examination will almost always reveal the presence of the tubercle bacillus.

Ætiology.—The inheritance of a lowered resistance to the invasion of the tubercle bacillus is an important factor, especially when such a tendency

exists in both parents. The sexes are equally affected. Tuberculous meningitis is rare during the first year of life, and especially during the first 6 months of life, when posterior basal meningitis is most common. Its greatest incidence is during the second and third years. It is common throughout childhood and early adult life, after which it becomes increasingly rare. The primary focus from which the organisms are spread to the meninges is most commonly a tuberculous mesenteric or bronchial gland.

Sometimes the source of infection is tuberculous disease of the lungs, of the abdomen, of the ear, of the joints, or of bone. Operations upon the sites of tuberculous disease may directly cause the dissemination of the tubercle bacilli, and especially surgical procedures upon tuberculous intracranial tumours, upon spinal caries, and upon tuberculous disease of bones and joints. The acute specific fevers, and especially measles, are sometimes the exciting causes of the disease. Injury to the head sometimes determines the attack.

Pathology.—In tuberculous meningitis three kinds of lesions of the meninges may be met with—(1) grey tubercles unassociated with inflammatory deposit; (2) tuberculous meningitis characterised by the presence of tuberculous granulations associated with a fibrinous and purulent exudation—the superficial tissue of the nervous system underlying the meninges is in this case always involved; (3) tuberculous tumours of any size up to that of a pigeon's egg. It is not uncommon to find such a tumour to be the focus of widely spread meningitis. The three kinds of lesions may coexist in the same case.

The flattening of the convolutions and the dry sticky feel of the surface of the brain are highly characteristic. The disease affects the pia-arachnoid and its processes, the small vessels entering the surface of the brain and the superficial tissues of the latter. Occasionally a few tubercles are found upon the inner surface of the dura mater. Generally the convexity of the brain escapes, or is little affected. In the intercrural space, around the optic chiasma, covering the tips of the temporal lobes, along the commencement of the Sylvian fissures and around the brain stem, there is an inflammatory exudation of tough consistency and of a pale yellowish-green colour. Spreading from the edge of this in decreasing numbers, grey tubercles are seen in the pia-arachnoid, particularly along the Sylvian fissures. If the fibrino-purulent exudation be examined by scraping where it is not too dense, or by opening up the Sylvian fissures which it firmly closes, it will be found to consist of grey and white tubercles which have become partly confluent, covered with a fibrino-purulent membrane. So firmly does this exudation cling to the brain tissue, that some of the latter comes away in the attempt to remove the affected pia-arachnoid. Miliary tubercles will almost invariably be found on the tentorial aspect of the cerebellum, and on the ependyma of the lateral ventricles. They may be found wherever the pia-arachnoid extends (the convexity; as a rule, excepted), but except at the base of the brain they are not, as a rule, accompanied by the characteristic tough exudation.

The brain as a whole is soft, and local softening of the walls of the ventricles, of the velum interpositum, and of the fornix is often present. This softening is caused by spreading of the tuberculous process from the pia-arachnoid to the small vessels of the surface of the brain, on the walls of which tubercles develop, sometimes in such numbers that a small entering vessel, when observed under low magnification, after the brain tissue has been removed

by careful washing, may resemble a bunch of grapes, each grape being a tuberculous nodule. Thrombosis is a common event in the vessels so involved, and softening follows. Some degree of thrombosis in the superior longitudinal sinus and in the veins of Galen is commonly present. It is probably owing to the softening of the nervous tissues that occlusion of the foramina by which the cerebro-spinal fluid leaves the ventricles does not often take place, and that, therefore, a condition of hydrocephalus does not occur in this form of meningitis. The cranial nerve palsies which are so frequently met with in this disease are the result of implication by adhesions and local interference with the blood supply of the nerves at the base of the brain, by the newly formed adhesive tissue. In the majority of cases the membranes of the spinal cord are affected, and the most common situation of the tubercles is upon the inner surface of the theca, and in the pia covering the lumbar enlargement.

Symptoms.—The onset is usually gradual, with signs of vague and slight illness. In children, general apathy and neglect of amusements and play, headache, loss of appetite, dullness, fretfulness, restlessness at night with grinding of the teeth during sleep, headache, vomiting and pyrexia are common symptoms. In older subjects, lassitude, depression, mental alteration, perversity and hysterical manifestations are common. Constipation is usually present, and the breath has a peculiar fœtor. The facial expression is one of illness and frowning discomfort, and there is disinclination to talk. Young children may be speechless for days together. As a rule, in this stage of the disease young children complain of nothing, and delirium is rare; but as age advances, delirium increases in frequency, and headache, usually frontal, is increasingly complained of. These slight and vague symptoms may last from a few days to several weeks, and constitute what has been called the prodromal stage of the malady. In those cases which are said to begin acutely, careful inquiry will generally reveal that some symptoms such as the above have preceded the acute onset. The further development of the disease is marked by the appearance of a lethargy, which soon deepens into a stupor, from which it is difficult or impossible to arouse the patient. Vomiting is of frequent occurrence, and headache may be severe. The child lies upon its side in the “cramped” position, resenting any disturbance. The expression becomes vacant, with wide-open eyes and dilated pupils, as if fixed upon some distant object. There is often some retraction of the angles of the mouth, and there is frequently a bright malar flush. In the later stages the limbs are generally extended and rigid. Stiffness of the neck is the rule, and head retraction may occur, but this is never so marked as in posterior basal meningitis. The abdomen is always markedly retracted and a *tâche cérébrale* is often conspicuous. A single sharp cry, apparently causeless, called the hydrocephalic cry, and which is common in all forms of meningitis and also in other infantile intracranial affections, is sometimes heard.

Ocular phenomena make their appearance towards the end of the first week of the developed disease. All varieties of varying and persistent strabismus and ptosis are met with, paralysis of the external rectus being the most common. Rolling movements and independent movements of the eyeballs may occur. The pupils may be contracted at first, and may show varying inequality, but in the later stages they are dilated. Papilloedema is almost

invariably present towards the end of the second week, if the patient survives so long. It is of moderate intensity, the height of the swelling rarely exceeding two dioptries. Choroidal tubercles sometimes occur.

Convulsions are common in every stage of the disease in children, but rare in adult cases. They may be the first symptom of the onset, but are more often met with in the later stages of the disease. They may be local or general. Repeated rhythmic movements are frequent, and are especially noticeable in connection with the mouth, where sucking and champing movements and grinding of the teeth are common. Rhythmic movements of the limbs may also occur. Coarse tremor upon movement of the limbs is the rule, and spasmodic twitching of the muscles is frequent. In rare cases, movements exactly like those of chorea occur. Kernig's sign is usually present.

As the disease advances, general paralysis of the limbs appears with rigidity in the extended position, with increased deep reflexes and extensor plantar reflexes. The deep reflexes generally disappear before death. The temperature is usually raised one or two degrees, but it presents no characteristic features, some cases being apyrexial throughout. Irregularity of the pulse is the rule, and is of considerable diagnostic importance. Rapid in the early stages, it tends to become unduly slow in the stage of coma, and again rapid as death nears. Cheyne-Stokes breathing and grouped breathing are common. Constipation is usually a marked and persistent feature.

Course.—The course of tuberculous meningitis is progressive to an invariably fatal termination in from a few days to 3 weeks after the appearance of definite symptoms, and no case of recovery is known to me in which the diagnosis has been unquestionably proved by the recovery of the tubercle bacillus from the cerebro-spinal fluid.

The end of the second week finds the patient emaciated, comatose and with papillœdema. Occasionally and more particularly in adults, marked remissions occur; for example, consciousness may be regained from a deeply comatose state, but such improvement is temporary. Death occurs quietly from asthenia, and may be hastened by the embarrassment which accumulation of mucus in the chest places upon the respiration and circulation.

The clinical course of tuberculous meningitis has been often described as consisting of four stages—(1) the prodromal stage; (2) the stage of irritation in which headache, convulsion, tremors and rigidity occur; (3) the stage of relaxation characterised by coma, flaccidity and loss of knee-jerk; and (4) the final stage of deep coma and paralysis. Such a division into stages, though useful as an aid to memory, is clinically inaccurate since it rarely, if ever, applies strictly to any particular case.

Diagnosis.—The early symptoms of the disease may give rise to difficulty in diagnosis, but the latter is relatively simple when the disease is advanced. The diseases liable to be confused with tuberculous meningitis at its commencement are gastro-intestinal catarrh, the exanthemata—especially enteric fever—and pneumonia. It must be borne in mind that in children convulsion, strabismus, head retraction and stiffness of the neck, with pyrexia, may be symptomatic of many maladies apart from meningitis, especially of apical pneumonia. In enteric fever the temperature is higher and the headache more severe, and irritability and resentment of interference are not present;

the decubitus is usually dorsal. Widal's test is of importance in this connection. When distinctive signs of intracranial disease have appeared the diagnosis has to be made from other forms of meningitis, sinus thrombosis, tumour, abscess and middle-ear disease. Careful examination of the retina and of the tympanic membranes is then necessary. In all cases the diagnosis must be made certain by the examination of the cerebro-spinal fluid, which will be found to contain lymphocytes in excess and tubercle bacilli. These organisms are sometimes difficult to isolate from the fluid, but their presence can be readily demonstrated by injecting the fluid into the subcutaneous tissue of guinea-pigs, when the characteristic lesion of tubercle results. It must be remembered that in some cases the polymorphonuclear leucocytes may be in excess, but these cases are at once distinguished from other forms of meningitis by the presence of numerous lymphocytes, by the absence of the meningococcus and of the other germs producing suppuration, and by the presence of the tubercle bacillus. Pirquet's skin reaction is often absent in tuberculous meningitis.

Treatment.—From the unvarying fatal issue of the malady, treatment can only be directed towards the relief of symptoms. Temporary improvement and relief of headache may be brought about by lumbar puncture, which may for this purpose be repeated several times. Bromides, chloral, aspirin and other analgesic drugs may be used to relieve the headache, check the convulsion and diminish the restlessness. Hexamine in large doses, inunction of mercury and administration of tuberculin have been largely used, but without any success. General treatment must be that which will secure such comfort as is possible for the patient. Where swallowing is difficult nasal feeding should be adopted.

PNEUMOCOCCAL MENINGITIS

Pneumococcal infection of the meninges most commonly follows upon a similar infection elsewhere in the body, empyema and pneumococcal otitis being the commonest lesions, while pneumonia, abdominal infection, abscess and joint infection are less common. In one-third of the cases, however, the meningeal infection is primary. The characteristics of the cerebro-spinal fluid are that it is purulent and sometimes so thick that it will not flow through the needle. It is greenish-yellow in colour, contains a large amount of albumin, and multitudinous polymorphonuclear cells, among which the characteristic pneumococcus is found.

Ætiology.—The disease may occur at any age. It is sometimes a terminal event of a pneumococcal infection elsewhere, and passes almost unnoticed, or is discovered only at the autopsy. Meningitis which follows operations upon the nose and disease of the nasal bones is usually of the pneumococcal variety.

Pathology.—The surface of the brain and spinal cord is highly characteristic. Usually the whole surface of the vertex and of the base is covered with a thick, tenacious, greenish-yellow pus, which is contained in the meshes of the arachnoid, and between this and the dura. The ventricles often contain pus. A similar exudation is found upon the spinal cord, more especially upon the dorsal aspect, and in the cervical and lumbo-sacral regions. The major affection of the vertex of the brain is the peculiarity

of this disease, and only in the rarest cases is the base alone affected. The exudation is characterised by the greater amount of fibrin than in other forms of meningitis.

Symptoms.—The symptoms are those which are common to all forms of meningitis. Some of the cases are indistinguishable symptomatically from cases of tuberculous meningitis. Others run a very rapid course and present few features other than headache, vomiting and pyrexia, with rapidly oncoming and quickly fatal coma. In others again, the meningeal symptoms are concealed in the terminal asthenia of a previously existing pneumococcal infection elsewhere, such as empyema, purulent pericarditis or peritonitis.

Diagnosis.—This rests upon the presence of signs of meningitis or the existence of coma alone, together with a cerebro-spinal fluid which is purulent from the presence of polymorphonuclear leucocytes, containing the pneumococcus.

No case of recovery from this form of meningitis has hitherto been recorded. Lumbar puncture and intrathecal injections of anti-pneumococcal serum may be performed, but on account of the thick nature of the exudate, little relief must be expected from the former, while the latter cannot possibly avail except in primary cases.

MENINGOCOCCAL MENINGITIS

See under Cerebro-spinal Fever, p. 152.

PYOGENIC MENINGITIS

Apart from meningococcal and pneumococcal infections, suppurative meningitis may result from the invasion of the meninges by staphylococci, streptococci, gonococci, *B. influenzae*, *B. anthracis* and streptothrix.

Staphylococcal and streptococcal infections are by far the most common. They may result in young children from septic conditions of the umbilicus and from infections of the skin. Usually they are due to extension of an infection of adjacent structures to the meninges, and follow disease of cranial and spinal bones, especially caries of the middle ear, erysipelas and other infections of the scalp, wounds of the meninges, especially bullet wounds, rupture of intracranial abscess, and they may occur in the course of a general septicaemia.

Pathology.—The pathology of these conditions does not materially differ from that of pneumococcal meningitis. In all cases the exudation is purulent, and in the meningitis due to *B. anthracis* it is of a red colour due to concomitant blood effusion. The cerebro-spinal fluid contains large numbers of polymorphonuclear leucocytes, together with the micro-organism responsible for each variety. Suppurative meningitis resulting from bone disease and from wounds of the meninges may be localised by the formation of meningeal adhesions, and an intrameningeal abscess may result. Such an abscess situated upon the upper surface of the temporal bone is not an uncommon result of caries of the middle ear.

The clinical aspect is that common to all forms of acute meningitis, high pyrexia, rigors and delirium being conspicuous. The course is rapid to an almost invariably fatal termination. In the localised form where drainage can be ensured and extension of the infection prevented, recovery should

take place. Several cases of recovery from gonococcal meningitis have been reported. Influenzal meningitis is invariably fatal.

Diagnosis.--This depends upon the presence of the clinical signs of meningitis and of a cerebro-spinal fluid containing polymorphonuclear leucocytes in large quantities, and upon the recognition in this fluid of the several micro-organisms responsible, by microscopic and cultivation methods. The recognition of *B. influenza* requires that cultures should be made upon some blood medium, for otherwise the organism may be easily overlooked and the fluid reported as sterile. Further, the presence of some well-known cause for suppurative meningitis, such as ear disease, staphylococcal infection, etc., suggests the diagnosis.

Acute otitis media may give rise to symptoms closely resembling those of meningitis, such as headache, pyrexia, vomiting, head retraction and delirium. In such cases examination of the ear, which should be made a routine in all cases where meningitis is suspected, will reveal tympanic distension, the relief of which is followed by a speedy disappearance of the symptoms. In this connection it must be borne in mind that meningitis and intracranial abscess never follow directly upon acute otitis, but they are the sequelæ of chronic otitis, which has resulted in caries of the temporal bone. When evidences of caries of the middle ear are present in a case presenting cerebral symptoms, distinction has to be made between meningitis and abscess of the brain or cerebellum. Here the presence of localising symptoms, either temporal or cerebellar, and the presence of papilloedema and any tendency to a temporary abatement of the symptoms point to the existence of an abscess, and further lumbar puncture will in all but the rarest cases settle the point. In cases of abscess in which cells and organisms are found in the cerebro-spinal fluid, these exist in small numbers only, as compared with the copious cells and organisms present in the fluid of suppurative meningitis.

Treatment.--In cases of meningitis secondary to temporal caries, the source of infection should be at once cleared out by surgical procedure. Repeated lumbar puncture may relieve symptoms, and injection of an anti-serum to the organism present may be tried. Vaccines may also be used. Hexamine in large doses may be given, since this drug appears in the cerebro-spinal fluid and exercises a decided inhibitory effect upon the growth of organisms.

SYPHILITIC MENINGITIS

Meningitis due to infection by the *Spirochæta pallida* is one of the characteristic lesions met with in practically all cases of syphilitic disease of the central nervous system, and plays its part in the production of the symptom complexes of these maladies, from acute cerebral syphilis and acute myelitis to general paralysis and locomotor ataxy. It may occur at any period after infection, but one-half of the cases occur during the first four years. In a few cases the symptoms have been noticed coincidently with the syphilitic roseolæ.

Pathology.--The morbid process consists essentially in an infiltration of the meninges with lymphocytes and plasma cells, spreading from the perivascular lymphatics where the spirochætes multiply freely, and it may lead to scarring and opacity of the membranes, with consequent strangling of the nerves and vessels and occlusion of the arachnoid space, or to massive

gummatous formation in the meninges. It is essentially a chronic form of meningitis though it may result in the production of acute symptoms. A marked feature is that the meningeal changes may be found actively progressive in one spot, and equally regressive in another. The disease may be local or diffuse, and it may attack the dura (pachymeningitis) and involve the overlying bone, or it may spread from the pia-arachnoid into the sublying nervous tissue (meningo-encephalitis).

The cerebro-spinal fluid is characteristic. It is usually under increased pressure, is clear and colourless, and contains lymphocytes and no other cell forms. The number of the lymphocytes present is in direct proportion to the activity of the meningeal syphilis. The spirochæte has rarely been found in the fluid, yet inoculation of apes with the fluid has proved successful.

Symptoms.—Apart from those conditions of nervous syphilis in which meningitis is associated with arterial disease, the formation of massive gummata and neuronie degeneration, syphilitic meningitis may be described as giving rise clinically to the following conditions :

1. *Headache.*

2. *Hydrocephalus.*—In those acute cases of cerebral syphilis characterised by rapidly oncoming headache, vomiting and papillœdema, mental reduction and somnolence without localising symptoms, and which respond readily to treatment, it seems certain that ventricular distension, consequent upon adhesive meningitis and ependymitis, is responsible. A more slowly oncoming ventricular occlusion may give rise to symptoms which cannot be distinguished from those caused by a non-localisable intracranial tumour. Syphilitic meningeal occlusion may give rise to typical hydrocephalus, and a considerable proportion of the cases of infantile hydrocephalus are of this nature and are due to congenital syphilis. A few cases are recorded in which chronic hydrocephalus of this nature has occurred in adult life.

3. *Infantile syphilitic meningitis.*—This is a chronic malady which commences insidiously during the first few months of life, with signs of general nervous deterioration. The appearance of the brain is very characteristic. The membrane over the vertex is opaque and thickened and adherent to the cortex. The gyri are shrunken, the sulci wide and the surface of the brain has in parts the appearance of wash-leather. The child does not get on, and takes an ever decreasing notice of its surroundings. Power of movement lessens, the limbs become rigid and the clinical aspect comes to resemble exactly that of a severe cerebral diplegia. Convulsions are of frequent occurrence. The diagnosis is not difficult, for the signs of meningitis are obvious and those of congenital syphilis may be present. There is an excess of lymphocytes in the cerebro-spinal fluid, both in which and in the blood there is a positive Wassermann reaction. The prognosis in any case where the symptoms have become marked is most unfavourable.

4. *Adult syphilitic meningitis* with a symptom-complex closely resembling that of tuberculous meningitis, has been reported on many occasions. In some of the cases the onset coincided with the appearance of the syphilitic roseola. The diagnosis depends upon the presence of signs of active syphilis, upon the cerebro-spinal lymphocytosis and upon the existence of a positive Wassermann reaction. The prognosis under appropriate treatment is good.

5. *Paralysis of cranial nerves.*—This common and often isolated symptom of nervous syphilis may result from sclerosing basal meningitis or from the presence of a gumma in the course of the nerve. Several of the nerves may be involved together in one patch of meningitis. Any of the cranial nerves may be affected from the olfactory to the hypoglossal, but the third or oculomotor nerve is by far the most frequently attacked.

Treatment.—The treatment of the above conditions is that appropriate for nervous syphilis in general (pp. 1489, 1490). The combined administration of mercury by inunction and of arsenic compounds by intravenous injection gives the best results. The intrathecal injection of salvarsanised serum has been largely advocated of recent years, but it is of doubtful value. Iodide of potassium is not nearly so useful as when massive gummata are present, and, moreover, it seems to increase the scarring process. Its use should be avoided until the patient has been under the influence of mercury for some time.

OTHER FORMS OF MENINGITIS

Meningitis due to the typhoid bacillus is a rare malady. It may occur as a primary disease, but is usually a complication in the course of enteric fever. It is to be remembered that while many cases of enteric fever present cerebral symptoms, in very few can meningitis be proved to exist. The meningeal exudation, generally serous, is sometimes purulent. The cerebro-spinal fluid contains lymphocytes, and Eberth's bacillus is present. The symptoms resemble those of acute meningitis in general. The diagnosis depends upon the presence of enteric fever, of Widal's reaction and the discovery of Eberth's bacillus in the cerebro-spinal fluid. The malady is generally fatal, but a considerable number of recoveries have occurred, especially in children. In rare cases symptoms of meningitis occur in the course of rheumatic infection, and Poynton and Paine have brought forward evidence that such symptoms are the result of infection of the meninges with the *Diplococcus rheumaticus*. The term "serous meningitis" is applied to those cases of meningitis in which the cerebro-spinal fluid is clear and sterile. In such cases recovery is the rule, and the symptoms are not rarely rapidly relieved by lumbar puncture. The term "meningism" is used for a group of cases which present symptoms of meningitis and in which no pathological change can be found either in the cerebro-spinal fluid, or, if death occur, in the meninges or cerebral tissue. It is met with in children in association with acute febrile diseases, and is presumably due to the toxin present. Recovery is usually rapid and complete.

W. J. ADIE.

CEREBRAL VASCULAR LESIONS

The central nervous system, situated within the cranial cavity, is supplied by four arteries, two upon each side. The large internal carotid arteries enter the cranial space external to the posterior clinoid process, give off the ophthalmic artery for the supply of the eye and orbit of the same side, and divide into the anterior and middle cerebral arteries, which roughly supply

the anterior two-thirds of the hemisphere. Obstruction of the internal carotid, either by embolism, thrombosis or pressure, produces a very characteristic symptom-complex in which there is blindness of one eye with retinal anæmia, and infarct from obstruction of the ophthalmic artery, together with hemiplegia of the opposite side from obstruction of the anterior and middle cerebral arteries. The distinctive term carotid hemiplegia is applied to this condition.

The smaller vertebral arteries derived from the subclavians ascend through the vertebral canals in the cervical transverse processes and enter the skull through the foramen magnum. Within the skull the vertebral arteries give off the important posterior inferior cerebellar arteries, which supply much of the cerebellum and also the medulla with its vital centres and its closely crowded conducting tracts. Obstruction of one of the posterior inferior cerebellar arteries is the common cause of the remarkable "cerebellar apoplexy" in which acute hemiataxy, medullary paralysis and hemianæsthesia appear suddenly.

The two vertebral arteries then join to form the basilar artery which occupies the middle line upon the ventral surface of the pons, and which gives branches supplying the whole of the pons and upper part of the brain stem. The basilar artery ends at the level of the crura cerebri by dividing into the posterior cerebral arteries, after having given off a superior cerebellar branch on either side for the supply of the upper cerebellum.

The vertebral and basilar arteries and their branches, previous to the division of the latter into the posterior cerebral arteries, are much less prone to disease causing symptoms than are the anterior, middle and posterior cerebral arteries, and consequently vascular lesions of the brain stem and cerebellum are infinitely more rare than are similar lesions of the cerebral hemispheres.

The anterior, middle and posterior cerebral arteries, soon after their commencements, are connected by the communicating arteries to form the "circle of Willis" in the sub-arachnoid space at the base of the brain. When the circle of Willis is perfectly developed, there is free communication between the three great cerebral arteries on each side, and it follows clinically that obstruction of any one of these vessels on the heart side of the circle of Willis will either occasion no symptoms of local cerebral lesion, or such symptoms will be transient because of the compensatory blood supply through the circle of Willis. It must, however, be most carefully borne in mind that the circle of Willis is often developmentally very imperfect—one or more of the communicating arteries being absent. For example, ligation of the internal carotid artery in man has quite often been followed by the appalling disaster of complete and irrecoverable hemiplegia.

The anterior cerebral artery supplies the prefrontal lobes, the orbital lobules, the anterior part of the caudate nucleus, and the whole of the mesial aspect of the hemisphere and corpus callosum as far back as the parieto-occipital fissure, with such convolutions as border on the middle line.

The posterior cerebral artery supplies the rest of the mesial aspect of the hemisphere, the inferior surface of the temporal and occipital lobes, the uncinate region and the posterior part of the corpus callosum, together with the corresponding edge of the convexity.

The middle cerebral artery supplies almost the whole of the convexity of the hemisphere, with the exception of the marginal supply of the anterior and posterior cerebral arteries. Its supply extends to the posterior pole of the hemisphere where there is an important communication with the supply of the posterior cerebral artery. The supply of the middle cerebral to the occipital pole of the hemisphere is of great clinical importance, for at the occipital pole central vision is represented, and the escape of central vision in destruction of the cortex of the cuneus, from lesions of the posterior cerebral artery and its calcarine branch is thus explained by the middle cerebral arterial supply to the posterior pole of the hemisphere.

The corpus striatum, optic thalamus and region of the internal capsule are supplied by the deep perforating branches of the middle cerebral artery, which arise as that vessel crosses the anterior perforated spot, and which are named lenticulo-frontal, lenticulo-striate and lenticulo-optic arteries respectively. The supply of these three arteries is terminal without conspicuous anastomosis.

The supply of the choroid plexuses of the lateral and third ventricles is from the middle cerebral, and that of the fourth ventricle from the vertebral.

The cerebral veins are for the most superficial, those of the convexity draining into the superior longitudinal sinus, those of the base into the cavernous sinus, and those of the posterior fossa into the lateral sinuses, while the large choroidal veins from the plexuses of the lateral and third ventricles run by the velum interpositum to the straight sinus. There is the freest intercommunication between the sinuses at the base of the brain, so that ligation of the lateral sinus upon one side does not disturb the vascular supply of the brain. On the other hand, there is no other way out for the blood of the convexity of the hemispheres than by the superior longitudinal sinus, and it is for this reason that blocking of this sinus always results in disastrous bilateral softening of the hemispheres.

The cerebral sinuses communicate freely with veins outside the skull by means of the orbital veins, the various emissary veins, of which the mastoid vein is the most important, and by the vertebral veins. Thrombosis of the cavernous sinus is accompanied by œdema of the orbit, and that of the lateral sinus, by œdema over the mastoid process.

The amount of blood within the skull case seems to vary but little under normal circumstances, though its rate of passage may vary greatly. When, however, the bulk of the intracranial content is increased either by new-growth, hæmorrhage or œdema, this can only occur in the closed skull at the expense of the cerebro-spinal fluid, of which there is normally very little, and which is expressed thereby, or at the expense of the amount of blood within the skull case, which is lessened thereby. The important fact follows, that whenever from such a cause the intracranial pressure is increased, there is relative ischæmia of the brain, and, further, that an increase of intracranial pressure is accompanied always by a rise of systemic blood-pressure to compensate for such ischæmia, provided that the vasomotor mechanism be intact, and that if owing to the failure of the vasomotor mechanism such a rise of blood-pressure does not accompany a rising intracranial pressure, death soon results. It is obvious that the intracranial pressure can never exceed the maximum venous blood-pressure in the cerebral veins, for under such circumstances the cerebral circulation would cease. An adequate

supply of blood to the brain is necessary for the retention of consciousness. When the blood supply fails from lowering of blood-pressure, as in fainting, consciousness is lost. Similarly, when a rapid increase in intracranial pressure occurs, consciousness is lost from the resulting cerebral anæmia, and this is the common cause of loss of consciousness in intracranial hæmorrhage, in cerebral thrombosis, for severe local œdema is the immediate result of thrombosis, and in abscess and tumour.

ANEURYSM

Pathology.—Miliary aneurysms, which are small seed-like dilatations of the finer arteries in the substance of the brain, are not uncommonly present in cerebral arterial degeneration. They are usually multiple. Much importance was formerly attached to miliary aneurysms as a common cause of cerebral hæmorrhage. The extensive researches of A. G. Ellis in 1909 and of Pick in 1910 have proved conclusively that miliary aneurysms are not a cause of hæmorrhage, and are of no practical importance apart from the associated arterial degeneration.

Larger irregular dilatations of the cerebral arteries are of frequent occurrence in connection with syphilitic and atheromatous vascular disease. They are of the nature of false aneurysms, are often of the dissecting type, and not unfrequently give rise to cerebral hæmorrhage. True aneurysms of the larger cerebral arteries are not uncommon, but they rarely reach a size larger than a small nut, and are most frequently unassociated with any symptoms during life. These may be grouped into the following order: (1) Congenital aneurysms which are attributed to local developmental imperfection in the vessel walls. These have been met with at all ages of life from early infancy upwards. Their size varies from that of a pea to that of a cherry. They are sometimes multiple. They are usually found upon the arteries in the vicinity of the circle of Willis, and especially at the junction of middle cerebral and posterior communicating arteries. They may also occur along the main cerebral trunks at some distance from the base. Most often such aneurysms occasion no symptoms during life, and are discovered only at autopsy; but they may rupture at any age, and are an important cause of cerebral hæmorrhage. Most important, they may leak and give rise to a clinical picture very different from that of rapid cerebral hæmorrhage. (2) Syphilitic aneurysms, which attain the largest size of all cerebral aneurysms, and which occur upon the *larger* vessels, especially upon the *basilar* artery. These may give rise to *pressure* signs, and may rupture. (3) Septic aneurysms from embolic infection of the arterial wall, of which the common cause is *infective* endocarditis. These are apt to be multiple. They are usually symptomless, but they may rupture. (4) Aneurysms which are usually of small size, not exceeding that of a small pea, due to arterial degeneration, are often multiple and always associated with extensive general atheroma of the cerebral arteries.

Symptoms.—Clinically, cerebral aneurysms fall into very definite groups—(1) Those which give rise to no symptoms whatever during life, but are discovered only upon necropsy. This group forms a large proportion of the cases. (2) Those in which the first indication of a cerebral lesion has been an apoplexy due to rupture of the sac, indistinguishable clinically

from other forms of cerebral hæmorrhage. (3) Those of which the peculiar symptoms of leaking aneurysm have been the only indications. (4) Those in which there have been signs of the presence of a cerebral tumour only. And lastly, (5) those in which symptoms of cerebral tumour have been followed by fatal apoplexy from rupture of a large sac. The last two groups are of rare occurrence.

It will thus be seen that a large proportion of the cases of cerebral aneurysm are symptomless. Among the remainder where symptoms occur, these are indistinguishable from those due to cerebral tumour, cerebral hæmorrhage, arterial degeneration, and infective endocarditis in general. There is, however, one clinical picture which may result from cerebral aneurysm which is definite and easily diagnosable, and that is when the aneurysm ruptures minutely and leaks slowly.

Leaking aneurysm (Spontaneous sub-arachnoid hæmorrhage).—It would seem to be the congenital aneurysm situated not far from the circle of Willis, which ruptures minutely and leaks slowly, and the escape of blood is usually into the sub-arachnoid space. Sometimes, however, the aneurysm becomes firmly adherent to the brain, and the escape occurs into the brain substance, and the symptoms are those of a slowly oncoming apoplexy.

In the first place, where the blood escapes into the meninges the clinical picture is very characteristic. The slowly escaping blood mingles with cerebro-spinal fluid, and in its course towards its exit in the spinal theca deposits fibrin and small clots around the nerve roots of the medulla and upper spinal cord, giving rise to pain and stiffness of the neck, which has been so considerable in several cases which I have seen as to cause the patients to have been treated for rheumatic stiff neck. Later, the continued slow outpouring of blood increases the intracranial pressure, and the medullary and spinal root irritation becomes greater, and headache, vomiting, head retraction and Kernig's sign appear. The symptom-complex at this stage exactly resembles a meningitis, but there is usually no elevation of temperature. Lumbar puncture reveals a cerebro-spinal fluid which is highly characteristic. It contains blood in quantity, and may be blood-coloured if the hæmorrhage is at all recent, or tends to a brownish colour if the bleeding is more remote. If the corpuscles are allowed to settle, or if the specimen be centrifugalised, the supernatant fluid is likely to be yellow or brownish in colour from altered blood pigment. A very large number of leucocytes may be present, since when blood is effused into the cerebro-spinal fluid the red cells are in time broken up, whereas the leucocytes persist. A differential count of the leucocytes will show that the proportion is exactly the same as in the patient's blood, thus excluding a meningitis.

As the hæmorrhage goes on, convulsions may occur, and the patient may become somnolent, apparently from the poisoning effect of the extravasated blood. At any time during the course of the case, which may last many days or even weeks, more rapid hæmorrhage may bring about the end with coma and general signs of high intracranial pressure, or the bleeding may cease and the symptoms abate or recover either permanently or temporarily, fresh hæmorrhages occurring weeks or even months later. The clinical pictures which may result from the escape of blood from an aneurysm into the meninges may be conveniently divided into three groups, which are determined by the rate and quantity of the blood escaping. (1) Severe

cases, in which the meningeal space is rapidly filled with blood and in which the aspect is that of cerebral hæmorrhage, except for the absence of local signs and for the immediate presence of profuse blood in the fluid withdrawn by lumbar puncture. In these cases it is usual to find on ophthalmoscopic examination large rounded subhyaloid hæmorrhages beneath the retina, which result from the pressure of the optic nerve sheath distended with blood. I have had one opportunity of observing the formation of these retinal hæmorrhages within three minutes of the rupture of the aneurysm. (2) Less severe cases, in which the above-described meningitic syndrome occurs. (3) Chronic cases, in which the escape is very slow or intermittent, which give an aspect of chronic headache and pain in the neck, perhaps with some stiffness of the neck, not suggesting meningitis. Obviously, all gradations between these varieties are met with.

In most of my cases, leaking of the aneurysm has occurred in the third or fourth decades of life. I have not met with a case in childhood, but I have seen one case at 17 years (recovered), one case at 18 years (fatal with necropsy), and also cases at 54 and 66 years (both fatal with necropsy).

Treatment.—This consists of absolute rest in the recumbent position. Repeated lumbar puncture should be employed and as much fluid as will run freely removed on each occasion. Any increase of the symptoms indicating increasing intracranial pressure should be an immediate indication for further drainage by lumbar puncture. Morphine, turpentine and calcium salts should be administered as possible aids to the arrest of the bleeding. Aspirin and the bromides are useful to combat restlessness and pain, while measures should be adopted to keep the blood-pressure low and without variations.

EMBOLISM

The majority of embolisms of the cerebral arteries occur in valvular heart disease, 89 per cent. (Saveliev). Embolism may also occur from detached portions of clot from an aneurysm, from thrombi in connection with atheroma or syphilis of the aorta, and from detached clots which may form in the region of the pulmonary veins and left heart where there is no cardiac valvular disease. This latter condition is not an infrequent cause of puerperal apoplexy. Embolism is rather more frequent in women on account of the greater incidence of mitral stenosis in that sex, and from the puerperal cases.

The embolus comes from the left heart and may be a vegetation from a quite recent endocarditis, but is more commonly a detached vegetation from a chronic and especially from an infective endocarditis. Very frequently it is a detached portion of clot which has formed in the left auricle in mitral stenosis. The middle cerebral arteries are the usual sites of lodgment of the emboli, and the left middle cerebral is rather more frequently affected than is the right. Embolism of the other cerebral vessels may occur but is extremely rare.

The pathological events which may follow the plugging of a cerebral vessel with an embolus are varied and are highly important. In the first place, secondary thrombosis may proceed from the embolus throughout the whole distal distribution of the vessel, and lead to complete softening of its area of supply, and the clinical aspect will be that of severe and unchanging

damage to the brain. The softened area may shrink or may undergo cyst formation, or it may be completely absorbed, giving rise to a porencephalus. Secondly, the embolus in the absence of secondary thrombosis may become adherent to one spot of the vessel wall at the site of its lodgment, and retracting from the vessel wall elsewhere, the blood channel becomes reopened, and the clinical results of the embolus, at first very severe, may disappear with unexpected and dramatic rapidity, and complete recovery ensue. Thirdly, the embolus may contract at the site of its primary lodgment, and become detached and shifted on by the blood stream to find a second resting place in a much smaller artery. This event is manifest clinically by rapid clearing up of the physical signs in many regions, with persistence or even deepening of the involvement of one particular region. For example, a severe and complete hemiplegia clears up suddenly on the third or fourth day, leaving a brachial monoplegia only. Fourthly, an embolus may be impacted at the termination of the internal carotid artery, giving rise to severe hemiplegia with blindness of the opposite eye from blocking of the ophthalmic artery—carotid hemiplegia. Owing to the re-establishment of the circulation by the circle of Willis the hemiplegia is likely to recover rapidly, while the eye remains permanently blind owing to secondary thrombosis extending through the ophthalmic artery. When an embolus is finally lodged and completely occludes the artery, the condition, both pathologically, clinically and from the point of view of treatment, is one of thrombosis, the cause of the embolism being taken into consideration. As with thrombosis, the immediate result of permanent occlusion is a condition of infarct and acute oedema in the region from which the blood supply is cut off. The acute oedema causes local pressure and increased general intracranial pressure, and is a common cause of the transient coma which often supervenes a few hours after the stroke, in both embolic and thrombotic apoplexy.

Stroke from embolism is the most suddenly occurring of all apoplexies, and the ictus is not preceded by any prodromal cerebral symptoms. Consciousness is apt to be lost at once if the whole middle cerebral artery be occluded, especially if the lesion be upon the left side. Or it may be retained throughout if the embolus lodge in a small vessel only.

Diagnosis.—This rests upon the occurrence of sudden apoplexy without prodromal symptoms in the presence of an obvious cause for embolism such as cardiac valvular disease, aortitis, pulmonary thrombosis or the puerperal state. The diagnosis can be a matter of probability only in those conditions where either embolism or thrombosis is likely, such as enfeebled cardiac states and the puerperal state.

Prognosis.—The prognosis in cerebral embolism depends upon the size of the vessel which is plugged, as deduced from the severity of the initial symptoms and their extent, and upon the immediate pathological changes which occur in the obstructed vessel as above described; and according to the nature of these changes, it may be the most severe and least recoverable, or, on the other hand, the least severe and most recoverable of all forms of apoplexy. The prognosis of the condition causing the embolism is often the more important.

Treatment.—The treatment is that of cerebral thrombosis together with that of the condition giving rise to the embolus.

ARTERIAL THROMBOSIS AND HÆMORRHAGE

Cerebral thrombosis and cerebral hæmorrhage seem hitherto to have been described in text-books of medicine as quite separate conditions, almost antagonistic and mutually incompatible, between which it was highly essential and even possible to make a differential diagnosis for the purpose of applying a very dissimilar line of treatment in the respective conditions, each line of treatment being the worst possible for the other condition. It cannot, however, be too forcibly pointed out, that primary arterial thrombosis and primary arterial hæmorrhage depend in every case upon degeneration of the arterial wall, and that every condition of degeneration of the arterial wall may cause either thrombosis or hæmorrhage indifferently. It is a usual experience to find in patients who have had several strokes that thrombosis was the cause of the earlier, and hæmorrhage of the final apoplexy. Even in that condition which has always been held to be the most important antecedent of cerebral hæmorrhage—renal disease with high arterial tension—Janeway has recently found that thrombosis and not hæmorrhage was the cause of apoplexy in many of his cases.

On account, therefore, of the identity of the underlying pathological condition in every case, and the clinical association of thrombosis and hæmorrhage of the cerebral arteries, and the difficulty of distinguishing them clinically, the two conditions are here described together.

Ætiology and Pathology.—The arterial degeneration which may result in cerebral thrombosis and hæmorrhage is due to the following causes: (1) Syphilis, which is the commonest cause of thrombosis in the first half of adult life, and which is less commonly the cause of hæmorrhage. It may affect both the large and the small arteries, even to the smallest. All the coats of the artery are affected, and in the case of the finest vessels there is conspicuous lymphocyte accumulation or "cuffing" round the vessel. In the neighbourhood of the affected vessels there is always syphilitic cerebritis in the form of lymphocyte exudation and œdema, and meningitis, if the lesion come to the surface. This is the most recoverable of all thrombotic lesions of the brain. (2) Atheroma, which is the common cause both of thrombosis and of hæmorrhage in the second half of adult life, and which is by far the commonest cause of hæmorrhage. It must be especially borne in mind that cerebral atheroma may be local in the cerebral vessels, and unassociated with general atheroma of the systemic vessels. (3) Arterial hypertrophy, with secondary focal degeneration of the media, with or without its commonly associated renal disease, which is of the nature of "small white kidney" in children and younger adults, and of the various types of "granular kidney" in older subjects. (4) Abnormal conditions of the blood, especially when associated with feeble cardiac action and low blood-pressure, as in the puerperal state, and in septicæmic conditions, and at the time of the menopause. (5) In association with new-growths of the brain, both thrombosis and hæmorrhage are common events, especially when the neoplasm is soft and rapidly growing. The vascular lesion may occur quite early in the course of the new-growth, and apoplexy may be the first sign of its presence. (6) Inflammatory conditions of any nature may cause thrombosis and hæmorrhage. The most important of

these are lethargic encephalitis and poliomyelitis, and more rarely tuberculous meningitis. The vascular lesions are usually small, but they may be extensive, and may cause death. (7) Traumatic lesions, such as the passage of a bullet through the brain, or a blow upon the head, or concussion from high explosives, may cause extensive thrombosis or hæmorrhage.

While cerebral hæmorrhage results often enough from the direct rupture of a true aneurysm, or of one of those irregular local thinnings of the vessel wall which is called a "false aneurysm," and may take place from an artery the wall of which is softened by disease though there be neither thinning nor bulging of the vessel wall, yet cerebral hæmorrhage is very often the direct consequence of thrombosis, and especially of thrombosis which has occurred some time previously. The sequence of events is as follows: An area of thrombosis occurs within the brain, and the usual softening and necrosis follow. On the confines of this area, the necrosis spreads to come in contact with the wall of a living and unthrombosed artery, perhaps of considerable size. The arterial wall of this vessel was nourished by the capillaries of the necrosed area, and with its nutrient supply now cut off there is local degeneration of the wall of the living artery. Moreover, the shrinking of the necrosed area of brain causes loss of support to the degenerate wall of the vessel, which ruptures as the result, under the influence of any sudden increase of blood-pressure. It is for this reason that one commonly finds in patients who have had multiple attacks of apoplexy, that the final and fatal attack is one of hæmorrhage, and that the preceding attacks have been attacks of thrombosis. In the autopsy room I have repeatedly been able to demonstrate antecedent thrombosis in cases of cerebral hæmorrhage. These spots of thrombosis, which cause hæmorrhage, need not be of large size, and they may be so small as hardly to cause symptoms on their occurrence. Marie first called attention to these small spots of thrombosis as *plaques jaunes*, small yellowish-brown spots, softened and sometimes cystic, and pointed out their importance as a cause of cerebral hæmorrhage. In a similar way the thrombosis of syphilitic arterial disease may cause subsequent hæmorrhage.

Syphilitic cerebral thrombosis is not usually a pure pathological process, for the vascular disease is often accompanied by acute syphilitic encephalitis, with much lymphocyte extravasation in the vicinity of the diseased vessels, and acute local œdema, which increase the evascularisation when thrombosis occurs. The symptoms of cerebral loss of function are not all due to the thrombosis, but are in part owing to the recoverable acute inflammatory condition, and it is for this reason that syphilitic apoplexy often shows much more recovery than do other forms of apoplexy.

Thrombosis is a more common cause of apoplexy than is hæmorrhage, but it is much more frequently survived, while hæmorrhage is nearly always fatal, within from a few hours to a few days of its onset. It follows therefore, that in the autopsy room of a general hospital, hæmorrhage is seen much more often than is thrombosis, while in infirmaries, where the survived cases of apoplexy collect, thrombosis is almost invariably the lesion found to be primarily responsible for the apoplexy.

Thrombosis tends to occur when the blood-pressure is low and the circulation less active, and is always strongly suggested when apoplexy occurs during sleep and conditions of quiet, and after exhaustion, exposure to cold,

severe purgation, and in debilitated states generally. It is preceded by slowing of the circulation in the area affected, and this may be productive of prodromal symptoms. Or there may be slight local thromboses preceding the main thrombosis, also giving rise to prodromal symptoms. Thrombosis may thus have an ingravescent onset, especially when clotting occurs in distal branches of an artery and extends towards the main vessel; but, on the other hand, it may have an absolutely sudden onset when the clotting occurs primarily in a large artery. The immediate effect of the thrombosis is a condition of infarct with œdema, extending widely in the vicinity, and it is this œdema which causes the loss of consciousness so commonly seen a few hours after the apoplexy has occurred. The œdema tends to pass off in a few days, and the area bereft of circulation by the thrombosis tends to become narrowed by collateral circulation from surrounding regions, and any recovery of function within the affected region must be by collateral circulation from elsewhere. The affected area at an early stage is bright red in colour, and soon becomes soft and shrunken (red softening). Later, the blood pigments degenerate with the production of bilirubin and are partly absorbed, producing a yellow-coloured lesion (yellow softening). Finally, much of the thrombosed tissue becomes necrotic and is absorbed, leaving one or several cystic cavities. These cavities are never so sharply defined as those resulting from embolism, because of the more complete necrosis occurring with the later lesion. Still, a severe arterial thrombosis occurring at an early age may result in a porencephaly. Cavities found in cases of apoplexy after years have elapsed, are too often attributed to hæmorrhage. In reality they are nearly all due to thrombosis or embolism. The cerebro-spinal fluid in thrombosis is never found to contain blood, but some little time after the apoplexy it is often coloured yellow or yellowish brown from escape of changed blood pigments, when the lesion has reached the surface of the convexity or the surface of the ventricle.

Hæmorrhage, which is usually described as an apoplexy of sudden onset, may be so when the escape is from a large vessel. When the bleeding commences from a smaller vessel, the symptoms are not sudden in their onset, but gather rapidly. Such a hæmorrhage is much like an avalanche. Commencing from a small vessel the hæmorrhage tears a small cavity, and in so doing opens up fresh bleeding points, and with increasing destruction more and more bleeding occurs from every piece of torn tissue, until the hæmorrhage reaches such a size as to burst commonly into the ventricle and much more rarely on to the surface. Indeed, it is difficult to conceive how a hæmorrhage into such a soft and vascular tissue as is the brain, should ever stop. As a matter of fact, it very rarely does so, but causes death in the first attack of hæmorrhagic apoplexy, within from a few hours to a few days after the onset, from widespread tearing up of the nervous system and bursting into the ventricle. One of the most important clinical distinctions between apoplexy due to thrombosis and apoplexy due to hæmorrhage is that the former is often survived, and that the latter is almost invariably fatal within a short time of the onset.

Hæmorrhage may occur anywhere within the nervous system, but its common seat of commencement is in the centrum semiovale, and the vessel which bursts is one of the perforating arteries, of which the lenticulo-striate which carries the name of the "artery of hæmorrhage" is the most common.

Such bleedings are often called "capsular hæmorrhages." It must be pointed out that this term capsular refers to the region outside the corpus striatum or external capsule, and not to the compact internal capsule as it converges to the crus cerebri. The cerebro-spinal fluid in cases of hæmorrhage contains blood within a very short time of the onset, and lumbar puncture often withdraws what is practically pure blood in large quantities. I have found blood present in large quantities very often within an hour of the onset.

Both thrombosis and hæmorrhage may occur in any part of the brain, while massive embolism is rare, except in the middle cerebral artery. The semioval centre, the calcarine region and the pons are the common sites of both hæmorrhage and thrombosis in that order of frequency. Hæmorrhage is rare except in these regions, while thrombosis is not uncommonly met with elsewhere.

Symptoms.—The nature of the symptoms in apoplexy will depend upon the site of the vascular lesion; and as the semioval centre or region of the middle cerebral artery is the commonest site for all the vascular lesions, hemiplegia is the common result; and this is associated with aphasia, if the lesion is in the left hemisphere, and involves or isolates the cortex. When the calcarine artery is the site of the lesion, hemianopia results; and this is apt to be accompanied by word-blindness, if the lesion be on the left side. Pontine apoplexy involves the appearance of double hemiplegia, bilateral ataxy and bilateral loss of sensibility, with signs of involvement of cranial nerve nuclei and cranial nerves. Cerebellar apoplexies and thrombosis of the posterior inferior cerebellar artery produce acute ataxy with forced movements and vomiting.

Prodromal symptoms in the form of transient weakness of one or both limbs of one side, transient aphasia and giddiness occur in thrombosis only. An ingravescent onset occurs in thrombosis only and when the clotting occurs in the periphery of arterial distribution first and spreads towards the main trunk. When commencing in the parietal region, tingling and numbness of an extremity first occur, followed by a spread of these symptoms over half of the body, and subsequent weakness deepening into hemiplegia. When commencing in the left temporal region gradually oncoming aphasia is first noticed, and when commencing in the ascending frontal convolution a peculiar sensation of heaviness in the limbs gradually increases until hemiplegia is obvious.

The onset in embolism is always instantaneous; it may be sudden in thrombosis, and in hæmorrhage from a large vessel. In hæmorrhage it is always rapid. Consciousness is lost or not, according to the severity of the initial lesion and the site it occupies, and to the magnitude of the processes which follow the initial lesion, namely, the œdema of embolism and thrombosis, and tearing of the brain tissue in hæmorrhage. In hæmorrhage, consciousness is lost soon, and the rapid development of severe symptoms which progressively deepen, is a most important early indication that this is the nature of the lesion.

In calcarine thrombosis the initial symptoms may be so slight as to pass unnoticed by the patient, whose first indication of defect may be, that he runs into objects on his blind side.

Convulsion sometimes occurs at the onset, and this nearly always indicates

thrombosis, rarely embolism, and never hæmorrhage. There may be some local spasm in the region of the cranial nerves in pontine hæmorrhage, but this is not convulsion.

Conjugate deviation of the eyes is a common feature of all apoplexy. Inasmuch as the lesion is irritative at its onset, and not too destructive, and always when convulsion occurs at the onset, there may be active conjugate deviation, the eyes being turned away from the side of the lesion and towards the paralysed or convulsed side in hemiplegic cases, or the blind side when hemianopia is present. But this active conjugate deviation lasts but a short while and is followed by a paralytic conjugate deviation in the opposite direction, both eyes being directed away from the paralysed side and towards the side of the lesion. This variety of conjugate deviation may last for a considerable time, but usually disappears with the onset of deep coma.

The pupils are often unequal; they may be contracted, or dilated widely, and may be insensitive to light. In severe apoplexy, when as the result of the cerebral shock or when hæmorrhage or œdema have so raised the pressure as to greatly reduce the physiological activity of all the intracranial elements with the production of deep coma, the pupils are widely dilated and insensitive. In pontine lesions, the pupils are often contracted to pin-point size, and this condition is of important localising significance.

In proportion to the severity of the general intracranial disturbance, respiration tends to be hurried, noisy and stertorous, and with increasing pressure to become irregular, grouped or of the Cheyne-Stokes type. The blood-pressure tends to be raised and the pulse full in all conditions of apoplexy, provided the heart will respond to the requirement of an increased blood-pressure in the face of an increased intracranial pressure.

Swallowing is often impossible, and the sphincters may be relaxed or retention may occur.

In the usual variety of apoplexy where the lesion is in the area of the middle cerebral artery and the local sign of the lesion is hemiplegia, it will be obvious that when the general intracranial pressure becomes severe and the coma becomes deep, the hemiplegia becomes less apparent, or masked by the universal condition of paralysis consequent upon the general intracranial condition. The physician often sees the patient for the first time when there is considerable coma, and he must determine upon which side the lesion is situated, and endeavour to have some perspective as to prognosis by determining the severity of the lesion.

The following points will serve to determine the side of the lesion when these signs are present : (1) The paralytic conjugate deviation is away from the side of the lesion. (2) The corneal reflex, when any is present, is diminished or lost on the hemiplegic side. (3) Painful stimulation will elicit less response or no response upon the hemiplegic side (hemianæsthesia). (4) The patient may respond by blinking to a feint made with the observer's hands towards the patient's eyes upon the sound side, and not on the hemiplegic side (hemianopia). (5) The limbs on the hemiplegic side when raised and allowed to fall passively, do so in a more lifeless, inert and flaccid fashion than upon the sound side. (6) And when there is any difference between the knee-jerks, abdominal reflexes and plantar reflexes, the former tend to be diminished and lost on the hemiplegic side while the plantar reflex will be of the extensor type on the hemiplegic side. It must be remembered in this connection, that a

severe lesion of one cerebral hemisphere abrogates for a time at least most of the functions of the whole hemisphere, and that the hemianæsthesia and hemianopia, here referred to, do not necessarily indicate that the destructive lesion involves the visual and sensory paths. And further, that the condition of coma due to increased intracranial pressure of itself causes such signs as bilateral loss of abdominal reflexes and knee-jerks, and bilateral extensor responses in the plantar reflex.

The severity of the lesion may be judged—(1) From the deepness of the coma; (2) from the degree to which the patient responds to any form of stimulation and from the general signs of nervous depression present—for example, a condition of complete bilateral flaccidity with complete loss of all reflex action and of all response to stimulation indicates a most severe lesion; and (3) from signs of failure of respiration as shown by irregular, grouped or Cheyne-Stokes breathing. It is further important to arrive at a determination if possible as to whether the condition present is stationary, deepening or showing signs of amelioration.

Vomiting is not an uncommon occurrence in the early hours of apoplexy and before coma becomes deep. Hyperpyrexia is often seen in fatal cases before the end. It is especially common and may reach a high degree in pontine apoplexy. It may be preceded by initial depression of temperature. It is of fatal prognostic import.

CEREBELLAR APOPLEXY.—This is usually the result of thrombosis of the posterior inferior cerebellar artery, which is a branch of the vertebral artery, and the clinical picture is very unlike that of cerebral apoplexy. The patient is seized with a sudden intense vertigo which carries him to the ground, as in Ménière's disease. Incessant vomiting and forced movements follow, the forced movements rotating the patient, so that he comes to rest prone, with that side of the face corresponding with the side of the cerebellar lesion in contact with the pillow. There is intense ataxy, usually bilateral at first, and later becoming confined to the limbs and trunk on the side of the lesion. The patient is unable to lift his head, or to maintain the sitting or standing position. When placed in such a position he positively dives to the ground when released. Nystagmus with the long slow movement to the side of the lesion, and a short fast movement in the opposite direction is conspicuous, and the skew deviation of the eyes is commonly seen. There is much general hypotonia of limbs and trunk which soon becomes limited to the side of the lesion. Head retraction, pain and stiffness of the neck and opisthotonos may occur. When the patient's condition recovers sufficiently to allow of examination, all the signs of a unilateral cerebellar lesion will be found. Consciousness is not often lost. Since the posterior inferior cerebellar artery also supplies the lateral region of the medulla, signs indicative of disturbance of this region are usually present, and these may dominate the clinical picture rather than the cerebellar signs. Chief amongst them are analgesia and thermanæsthesia of the face and head, due to implication of that part of the spinothalamic tract which is as yet uncrossed at this level, and of the limbs and body upon the opposite side, due to involvement of that part of the spinothalamic tract which has crossed below this level. Between these two areas of sensory loss there is often a gap where sensibility is normal, corresponding with that part of the spinothalamic tract which is crossing obliquely at this level, and therefore is too near the middle line to be affected. Paralysis of

the motor vagus is often found from involvement of the nucleus ambiguus, and, from the extension of the lesion or of consecutive oedema towards and across the middle line, sometimes causes severe dysphagia and dysarthria, and one of the great dangers of this form of apoplexy is extension of the thrombosis to that part of the medulla which contains the respiratory and other vital centres. When, however, such extension does not take place, and if the destruction of the lateral lobe is not too extensive, the most remarkable recovery may take place. Compensation in other structures for moderate cerebellar destruction seems to occur readily and rapidly.

Diagnosis.—*The nature of the lesion.*—Embolism should be diagnosed in all cases where there is an obvious cardiac valvular lesion, particularly mitral stenosis, septic endocarditis, aortic disease and aneurysm. It is true that syphilitic cerebral thrombosis may occur with syphilitic aortitis, but the combination is rare, for syphilitic aortitis usually occurs at a much later age than does syphilitic cerebral thrombosis.

Further conditions of cardiac feebleness and corresponding feebleness of circulation must obviously predispose to thrombosis if arterial disease be present. Mistakes in diagnosis will, however, not often occur, and they are not of moment to the patient, for embolism when once the embolus is lodged is for all purposes of treatment and prognosis the same condition as is thrombosis. Thrombosis should be diagnosed in all primary apoplexies in young syphilitic subjects, for syphilitic hæmorrhage usually occurs at some time considerably subsequent to a syphilitic thrombosis. In this connection the serum reaction and the cytology and reactions of the cerebro-spinal fluid are all-important in the diagnosis.

Thrombosis should be diagnosed, notwithstanding the presence of high arterial tension or renal disease, in all cases of apoplexy without organic cardiac valvular disease, when the onset occurs during sleep or under circumstances of quiet, depletion or exhaustion, and in all cases where prodromal symptoms are marked, or where the onset of the apoplexy is gradual, and in apoplexies occurring in advanced age, for then hæmorrhage is almost unknown. All slight apoplexies and nearly all those that survive the first 10 days after the ictus, are due to thrombosis.

Puerperal apoplexy and that occurring at the time of the menopause in women are mostly due to thrombosis.

When the cerebro-spinal fluid obtained by lumbar puncture shows an absence of blood a few hours after the ictus, thrombosis is highly probable, and hæmorrhage is very unlikely. Hæmorrhage is a likely cause of apoplexy, occurring during exertion, especially if it occurs at a moment of severe physical strain, or at the height of passion. It is always a probable lesion in cases where a previous thrombotic apoplexy has occurred, the final event, where multiple strokes have succeeded one another, being almost invariably hæmorrhage. An apoplexy with rapid onset and with symptoms rapidly deepening, with a quick onset of deep coma, and the development of pyrexia and signs of respiratory failure, is usually due to hæmorrhage. The certain test that an apoplexy is due to hæmorrhage is the presence of blood in quantity in the cerebro-spinal space as proved by lumbar puncture. In cases of small white kidney in the young and of granular kidney before the age of 50 years, where the blood tension is very high, and where there is severe retinitis, hæmorrhage is the most likely cause of stroke.

The position and extent of the lesion.—The position of the lesion may be judged by the nature of the initial signs, whether visual, sensory, motor or aphasic, cerebellar or pontine, and later by the permanent symptoms resulting from the lesion. It must be carefully borne in mind in this connection, that a severe lesion of a cerebral hemisphere may entirely abrogate the functions of that hemisphere, initially by a process of shock and afterwards by the occurrence of œdema in the vicinity of the lesion, which may spread widely.

The extent of the lesion may be gathered by the severity or otherwise of the early symptoms and their rate of increase, and by early or immediate loss of consciousness, and by the completeness of the paralysis resulting. The more severe the extent of the lesion the sooner do grave signs of general cerebral failure appear.

Differential Diagnosis.—The diagnosis of coma due to a cerebral vascular lesion is usually made without difficulty from the history, and from the presence of unequivocal signs of local lesion of the brain. In a patient without history, and when the coma has become so deep as to remove the unilaterality of physical signs, from the severity of the general intracranial pressure, the diagnosis may be difficult from other causes of coma such as uræmia and diabetes, poisoning by opium, alcohol and its derivatives and illuminating gas, and in cases of difficulty search is to be made for the usually obvious signs of these conditions. Uræmia may present especial difficulties, for it is often associated with cerebral vascular lesion, and transient hemiplegic attacks may occur in this condition. Absolutely sudden death which is so often recorded in death certificates as due to apoplexy, is usually associated with a stoppage of the heart following the obliteration of one of its coronary arteries. Apoplexy never causes sudden death. There is one recorded case of death from cerebral hæmorrhage in five minutes, but it is rare in any apoplexy for death to occur in under 2 hours. Other conditions causing hemiplegia with coma must be taken into consideration. Epilepsy and especially hemi-epilepsy may be followed by marked unilateral paralysis (Todd's paralysis), which may last for a considerable time. Here the history of recurring attacks and the complete recovery will easily prevent confusion.

Hysterical attacks may show a superficial resemblance only to apoplexy, and are to be distinguished by the absence of any signs of organic disease. Cerebral malaria and sunstroke may closely resemble apoplexy, and should always come to mind when rapid coma follows the development of cerebral symptoms in circumstances where these causes are likely.

The congestive attacks of general paralysis of the insane are peculiarly difficult to diagnose from apoplexy. Perhaps they are due to suddenly occurring acute cerebral local œdema. They are liable to mistaken diagnosis, of course, only when occurring as the initial manifestation of the disease. These attacks take the form of rapidly occurring attacks of hemiplegia, aphasia, hemianopia, hemianæsthesia or of some combination of these conditions, usually associated with initial convulsions and followed by coma. The diagnosis of a syphilitic thrombosis is made with reason on the positive serum reactions, and cerebro-spinal fluid examination. If energetically treated it recovers with marvellous rapidity and completeness, to slowly develop the characteristic signs of general paralysis. It is the too rapid recovery in a case of apparent syphilitic thrombosis which should suggest the possibility of the stroke being a congestive attack in general paralysis

of the insane. In all cases of coma without history, especially when there are signs of local cerebral involvement, a very careful examination of the head should be made for traces of recent injury, and if signs of injury be found, the skull and meninges should be opened, and the nature of the lesion sought out and dealt with surgically.

Prognosis.—A majority of the cases of apoplexy from syphilitic thrombosis make a fair recovery, which obviously depends upon how much permanent thrombosis occurs in the lesion of acute syphilitic encephalitis which is responsible for this condition, and upon the early application of appropriate treatment for syphilis. In some of these cases even, no recovery occurs.

In embolism the course and prognosis depend upon the extent of the vascular supply cut off when the embolus comes finally to rest; and upon the amount of collateral circulation afforded, and upon the cardiac condition.

In thrombosis due to atheroma the apoplexy may be rapidly fatal from extension of the thrombosis and secondary œdema, which raise the intracranial pressure beyond the limits of survival. In cases which survive, considerable recovery may occur in proportion to the extent of the lesion, but in these subjects an apoplexy is usually the beginning of the end, since the underlying pathological causes, arterial disease and failing cardiac action, still exist and are not amenable to any radical treatment. It is astonishing, however, how many of the cases of apoplexy due to atheromatous thrombosis survive for years without any recurrence of the thrombosis or occurrence of hæmorrhage. In cases of hæmorrhage, the immediate prognosis is the gravest possible, the great majority of the cases surviving but a few hours.

Cerebellar thrombosis is a dangerous condition from the risk of extension of the thrombosis to the vital centres in the medulla, but if the acute stage passes without this untoward event, complete recovery may occur in those cases where the lesion is not very extensive, and recovery of working capacity is usual, even in more severe cases. A good many of the cases are, however, immediately fatal.

Treatment.—When arterial disease is known to be present, the only measure which can in any way tend to safeguard the patient from apoplexy is moderation in all things: in diet, alcohol, mental and physical exercises, and above all moderation in all measures tending to lower the blood-pressure, for hæmorrhage is due not so much to the immediate high blood-pressure as it is to an antecedent period of low blood-pressure in a high tension subject, which has allowed of thrombosis and which, when the tension is high, at some subsequent period causes rupture of a vessel in the thrombosed area. It is highly probable that no treatment influences the course and fatal issue of apoplexy due to hæmorrhage except surgical treatment. Cushing has urged that cerebral hæmorrhage should be treated surgically, and has performed this operation upon a number of cases with some degree of success. The difficulty is that hæmorrhage occurs so rapidly, and the cerebral destruction becomes so great during the first hour of the hæmorrhage. Even in cases of thrombosis and embolism which are severe, Cushing advocates exploration and decompression on the correct grounds that the immediate danger of death in these conditions is due to œdema raising the intracranial pressure beyond the survival limit. Thrombosis and embolism, however, allow some scope for medical treatment, which should be the same in the two

conditions; and as I have argued above that medical treatment in cases of hæmorrhage is useless and cannot avert the fatal result, I advise one line of treatment to be taken in all cases of apoplexy.

From the onset of symptoms in every case, a careful stimulant line of treatment must be adopted, and all depletive measures that may be calculated to lower the blood-pressure and diminish the force of the cardiac action should be scrupulously avoided. It has been pointed out in the preceding passages how much the local and general symptoms of apoplexy are the result of cerebral ischæmia produced by the raised intracranial pressure, either from hæmorrhage or from cedema, and how nature attempts to combat this ischæmia by a reflex raising of the blood-pressure, to keep the cerebral circulation going, and that how when the intracranial pressure exceeds that of the mean intracranial venous pressure, death must at once result from stoppage of the cerebral circulation. As Thomas truly emphasises, "How can the lowering of arterial blood-pressure possibly help such conditions?" Absolute rest is, in the first place, essential when prodromal symptoms appear, and at the onset of an attack diffusible stimulants in the form of alcohol and liquid food; the heart's action may be improved by strychnine, while restlessness may be combated with bromides. If the patient is conscious, he should make as little effort as possible. His head and shoulders should be raised, special care being taken that the neck is not bent, and that nothing shall interfere with the return of blood from the head. If there is unconsciousness with stertor, the head and shoulders should be turned upon one side, so that the tongue should not fall back and impede respiration. If there be much cyanosis from impeded respiration, as is often seen in plethoric subjects, it is advisable to withdraw blood by venesection, for such relief of embarrassment acts as a stimulant to the circulation. Purgation should be avoided, and the bowel relieved at intervals by enemata. Stimulating food in a liquid form should be administered with stimulants at regular intervals; and if there is any difficulty in swallowing, the food should be administered with the nasal tube. The bladder should be carefully watched from the first, lest retention should occur, and the catheter passed when necessary. Lumbar puncture should always be performed for diagnostic purposes, and it frequently gives relief from symptoms due to the high intracranial pressure. I have many times seen consciousness return within a few minutes of lumbar puncture, when much fluid can be withdrawn. It is advisable to withdraw all the fluid which will run out at a rate above the normal. When bloody cerebro-spinal fluid or pure blood is met with, the lumbar puncture should be frequently repeated for the relief of symptoms. Bed-sores and hypostatic bronchitis must be avoided by the usual measures. In the cases that survive the first few days, passive movements should be used daily to all the joints of the affected side in hemiplegic cases; for this will obviate the painful rest adhesions which form in the joints of the paralysed limbs, and especially in the shoulder joint, and subsequently cause so much pain and misery to the patient. With returning power, massage and passive movement should be used to the affected limbs, but electricity should not be used, since it tends to increase spasticity. A hemiplegic patient after apoplexy, should be got upon his legs and encouraged to make attempts to walk as early as ever the returning power allows any possibility of the attempt.

SINUS THROMBOSIS

Thrombosis of the cerebral sinuses may occur rarely as a primary condition, or it may be secondary to infective processes spreading to the sinuses from contiguous infected regions.

Ætiology.—Primary thrombosis is a rare condition. It is said to affect the superior longitudinal sinus most commonly. It is more common in the first year of life than at any other period, when it may follow diarrhoea, bronchitis or the conditions of exhaustion met with in tuberculous disease and in congenital syphilis, and it may follow acute diseases such as measles, diphtheria, etc. It occurs after puberty especially in connection with anæmic states, and particularly with chlorosis. In chlorosis, among 82 cases of cerebral thrombosis, 78 cases were of venous thrombosis and 32 were cases of sinus thrombosis. Such cases are said to be often fatal. It may also occur at any age, up to advanced old age, in the terminal stages of cancer, phthisis and other chronic diseases.

The essential cause of secondary thrombosis is the advent of micro-organisms to the sinuses. The infection is often a mixed one, but the common organisms present are streptococcus, pneumococcus and *Bacillus coli*. The sinus may become infected as a part of a general pyæmia, or infection may spread directly through its wall from a focus of local disease, most commonly from an extradural abscess. In most cases, however, the sinus becomes infected from a local spreading septic thrombosis of the veins which open into the sinus, from an infected spot at a distance. Thrombosis of sinuses may also occur from injury, as by bullet wounds and fractures of the skull, and may also result from surgical procedures in the region of the sinuses.

Pathology.—The affected sinus is bulged and distended, and feels to the touch as if it were injected with a solid mass. In the infective forms, the clot may very quickly break down into pus, and general pyæmia result. When the superior longitudinal sinus is thrombosed, there is marked congestion of the convolutions of the convexity of the brain, often with cord-like clot-distended veins. There is bloody serum in the sub-arachnoid space contaminating the cerebro-spinal fluid withdrawn by lumbar puncture. Later, there is extensive bilateral softening of the cerebral hemispheres, most marked in the paracentral and surrounding convolutions. The cavernous and lateral sinuses do not drain the brain directly, and blocking of one of them does not cause so much cerebral disturbance, on account of the presence of alternative paths for the blood. Thrombosis of the cavernous sinus, however, may extend to the ophthalmic veins and cause blindness with an anæmic and infarcted condition of the retina. The nerves which lie in its outer wall, namely, the third, the fourth, the ophthalmic division of the fifth and the sixth nerves, may be paralysed.

Symptoms.—The clinical aspect of this condition is made up of three groups of symptoms—(1) the general signs of some bodily condition likely to be associated with thrombosis, such as marasmus, chlorosis, pyæmia, local cranial injury or septic disease of cranial bones, and neighbouring tissues; (2) general signs of intracranial disturbance, which will depend upon how much the cerebral circulation is upset by the blocking, and which will be severe in cases where the superior longitudinal or the straight sinus

is affected, and perhaps altogether absent where the cavernous sinus or the lateral sinus is affected; and (3) local signs of blocking of an individual sinus.

The general signs depend upon congestion, œdema, meningeal exudation and increased intracranial pressure. Headache, drowsiness, deepening into coma, and vomiting are common, while delirium and convulsions may occur. Papilloedema is not infrequent, while head retraction and rigidity of the neck, trismus, strabismus, inequality of the pupils, nystagmus, and irregularity of pulse and respiration may occur. In infective thrombosis, high pyrexia and rigors are the rule.

LOCAL SIGNS.—*Superior longitudinal sinus.*—The general signs are severe and convulsion is common, and bilateral hemiparesis or paralysis is likely to develop. There may be cyanosis and œdema of the forehead. The angular parietal and temporal veins may be distended, and in rare cases thrombosed.

Lateral sinus.—The clot may extend into the jugular vein and cause pain and stiffness on that side of the neck, and occasionally the thrombosed jugular vein may be felt beneath the anterior border of the sterno-mastoid as a tender solid cord. There may be tenderness and swelling over the region of the mastoid emissary vein.

Cavernous sinus.—There is œdema of the orbit, with proptosis and œdema of the conjunctiva, forehead and face. Amblyopia or blindness is the rule. Ophthalmoscopic examination reveals swelling of the disk with multiple hæmorrhages. Paralysis of the ocular muscles and anæsthesia of the eye on the same side may also occur.

Diagnosis.—If local signs, which give conclusive external evidence of sinus thrombosis, are absent, it may be very difficult to distinguish this condition from meningitis, abscess, encephalitis or other intracranial lesions. The septic forms of meningitis should be distinguished by the polymorphonuclear leucocytosis in the cerebro-spinal fluid. It must be remembered, that in the primary forms of sinus thrombosis in children, a copious lymphocytosis is met with, which may cause confusion with tuberculous meningitis. Abscess and sinus thrombosis often exist together.

Prognosis.—This disease is, as a rule, rapidly fatal from ever-increasing intracranial pressure; but some subjects, both in the non-infective and in the infective forms, survive. This is especially the case when the thrombosis is confined to one cavernous sinus. Cases of infective thrombosis of the lateral sinus following middle-ear disease have often been saved by timely surgical interference with ligature of the jugular vein and of the lateral sinus on either side of the thrombosed area, and with incision and turning out of the clot.

Treatment.—Beyond vigorous prophylactic measures against the causes of this condition and the palliative treatment of symptoms, surgical measures in cases of local infective origin alone are of avail. Further, in dealing with injuries of the skull in the region of the superior longitudinal sinus, trephining and exploration should be undertaken with a clear understanding of possible thrombosis of the sinus, and its appalling results.

APHASIA AND OTHER DEFECTS OF SPEECH

GENERAL CONSIDERATIONS.—The function of speech, which is the highest and most recently evolved human function which we have any means of directly analysing, has as its anatomical substratum a region of the cerebral convolutions situated in the left hemisphere and having its centre a little behind the middle of the first and second temporal convolutions. It is limited above by the posterior limb of the Sylvian fissure, occupies probably the tip and the whole external convexity of the left temporal lobe, and spreads backwards into the supramarginal and angular gyri, while it extends forwards over all the convolutions of the insula and possibly to the posterior ends of the second and third pre-frontal gyri of the left side.

This "speech region of the brain" comprises not only the cortex but also the subcortical white matter which carries the paths of communication between the speech region and other parts of the brain. Posteriorly it receives an important white tract which conveys incitations from the visual region of the cortex situated in the cuneus and posterior pole of both cerebral hemispheres. An interruption of this tract results in the condition known as "pure word blindness," or inability to appreciate written speech. Upon its deep aspect the speech region of the convolutions receives the temporal projection of fibres conveying the auditory impressions, and destruction of this system by a lesion undercutting the convolutions in the centre of the temporal lobe produces "word-deafness," or inability to appreciate spoken language. In this same region another set of afferents impinges upon the speech area which convey the muscular sense impressions and other sensory impressions which are produced in the movements of articulation and which are the only guidance which the "deaf mute" has in the knowledge of correct execution in his articulation.

A lesion deep in the temporal lobe which interrupts both the foregoing paths, isolates the speech region from any appreciation of correct execution, with the result that spoken language becomes unshapen and degenerates into a voluble jargon, "jargon aphasia."

In the anterior half of the speech area a tract of white fibres gathers by degrees, and passing forward constitutes the bulk of the "temporal isthmus," which joins the temporal lappet to the insula, and runs beneath the insula to the region beneath the first and second pre-frontal convolutions, from whence it is connected with the pyramidal path of the left side, and by way of the corpus callosum with the pyramidal path of the right side. This is the executive outgoing path for speech impressions and a complete lesion of this path, as by a limited subcortical lesion underlying the posterior end of the left third pre-frontal gyrus and anterior part of the insula, will result in complete inability to exteriorise either spoken or written speech—"pure aphasia" and "pure agraphia."

In the speech area of the brain thus limited, little or nothing is known of any localisation of function. It is generally held that there is a gradual passing over from receptive function (appreciation of spoken and written language) in the posterior regions, to executive function (exteriorisation of spoken and written language) in the anterior regions. And even this vague localisation is probably due to the fact that the incoming tracts from the

visual, auditory and sensory systems which join the speech area in its posterior half and the outgoing tract which leaves it anteriorly, neither end abruptly nor gather abruptly, but do so gradually, and therefore lesions of the posterior region will interfere more with the receptive paths and those of the anterior region with the outgoing path.

Inasmuch as the phenomena of "word-blindness" and "word-deafness," as well as executive "aphasia" and "agraphia" result from lesion of the speech area, these seem to result from lesion of the tracts concerned and not from interference with the function of the cortex. These phenomena are of common occurrence in connection with lesions of the speech region and, in the hands of Broca, Wernicke, Kussmaul, Lichtheim and others, lead to the formulation of localised areas of the cerebral cortex with specific functions in regard to speech. Thus, Broca's centre in the cortex of the posterior part of the left third pre-frontal convolution was the motor centre for spoken language, while Exner's centre in a similar position in the second left pre-frontal gyrus was the motor centre for written language. The "auditory word-centre" in which auditory memories of words were stored was in the cortex of the first and second temporal gyri, and the "visual word-centre" in which visual memories for words were impressed was in the cortex of the angular gyrus. These various centres were connected together by to-and-fro paths which could be separately affected by a lesion, and the attempt was made to explain the multitudinous and varied phenomena which occur in lesions of the speech region by damage to one or other of these hypothetical word-centres or to their connecting paths. The result was highly unsatisfactory, for the cases generally refused to correspond with the theories clinically, and practically never corresponded pathologically. Dejerine, by his discovery that a subcortical lesion in the right place could produce "pure aphasia and agraphia" at the front end of the speech area and "pure word-blindness" at the posterior end, the cortex being intact, went far to make untenable the theories of narrow localisation of function within the speech centre. Subsequently the work of Pierre Marie, Head and others has placed modern conceptions of speech function upon a less artificial basis.

The speech function seems to be concerned with the left hemisphere of the brain alone in right-handed persons, and this is explained by the major potential of the left hemisphere for receptivity and education associated with the major use of the right hand through the countless ages of humanity. Left-handedness is usually associated with a transfer of the speech function to the right hemisphere, but there are exceptions to this rule.

The possibility of the transference of the speech function from the left to the right hemisphere is great during childhood, to the extent that no lesion of the speech region of the left hemisphere, however extensive, causes lasting loss of speech in a child under the age of six years, provided sufficient intelligence remain. After this age the possibility of such compensation by the right hemisphere for lesions in the left hemisphere seems gradually to diminish and to occur but little after adult life is reached, but even in adult life remarkable exceptions to this rule are seen.

The descending paths from the brain by which speech is executed are the pyramidal paths. The pyramidal fibres for the movement of lips, tongue, larynx, etc., are situated exactly at the knee of the internal capsule, and bear the name "geniculate fascicle." The speech area of the cortex seems

to command both right and left pyramidal systems equally, so that no lesion of one pyramidal system is ever productive of speech defects, either aphasic or dysarthric.

From this it follows that aphasia, word-blindness, word-deafness, amnesia, etc., only result from lesions of the convolutions and of the white matter closely underlying the convolutions, and never from lesions of the deeper parts of the corona radiata and capsules.

When, however, both pyramidal systems are involved, as, for example, by bilateral lesions of the brain, or by lesions of the brain stem which involve both pyramidal systems where these are contiguous, or by neuronie degeneration of the pyramidal systems in general, then defects of speech execution arise comparable to the spastic paralysis of hemiplegia. These do not concern the pattern of speech, but solely the articulation, which becomes slow, clumsy, and slurring and indistinct, from weakness of movement, stiffness of the muscles concerned, and inability finely to adjust the stop positions at which the consonants are made. This condition, which is known as "spastic dysarthria," is commonly met with in double hemiplegia, in lesions of the brain stem involving both pyramidal tracts, and also in the tonic form of progressive muscular atrophy. In older writings it is often referred to under the most inappropriate name of "pseudo-bulbar paralysis."

When the lower motor neurons subserving the speech mechanism are bilaterally affected, a very similar dysarthria results, from the weakness and inaccuracy of the movements thus entailed, which is known as "flaccid or atrophic dysarthria," and which is met with in lesions of the medulla oblongata of all kinds, in progressive muscular atrophy, and in peripheral neuritis.

Lesions of the vermis of the cerebellum and of the cerebellar connections of the medulla oblongata are productive of a peculiar defect of articulation, "ataxic dysarthria," in which slurring, syllable-stumbling, syllable-elision and undue separation of syllables are conspicuous, and this sometimes deserves the name often used for it—staccato or syllabic utterance. Ataxic dysarthria is common in disseminate sclerosis, Friedreich's disease and in cerebellar disease. Aphonia, which is the loss of the vocal element in speech, the articulatory being preserved, is met with in bilateral complete paralysis of the larynx, as a reflex condition in affection of the vocal cords and as an hysterical manifestation. Mutism is invariably a symptom of hysteria.

VASCULAR SUPPLY.—The speech area of the left cerebral hemisphere is supplied almost exclusively by the left Sylvian artery, the anterior branch of which supplies the posterior ends of the second and third pre-frontal gyri, the anterior part of the insula, and the sub-lying white matter. Lesions of this branch are apt to destroy the subcortical white matter containing the out-going path from the speech area—the so-called "motor aphasia," "Broca's aphasia," or "pure aphasia" resulting, according to the exact situation and extent of the lesion. The posterior branch of the Sylvian artery running in the Sylvian fissure supplies the rest of the speech area, and lesions of this vessel are productive of the so-called "sensory aphasia," "Wernicke's aphasia," or "total aphasia," according to the extent of the lesion. There is, however, a deep branch of the posterior cerebral artery,

via the calcarine artery, which supplies the white matter beneath the posterior limits of the angular gyrus, and a lesion of this branch, by severing the incoming path from the visual area in the cuneus to the speech area, may cause "pure word blindness" as an isolated phenomenon or in conjunction with right hemianopia.

LESIONS RESPONSIBLE FOR APHASIA.—By far the most common cause of aphasia, in all its degrees and varieties, is vascular disease, usually thrombosis, less commonly embolism, and only in the rarest cases hæmorrhage—for the reason that the two former lesions often affect the vascular supply of the superficial parts of the hemisphere, whereas hæmorrhage is generally situated deeply; moreover, cases of cerebral hæmorrhage rarely survive the occurrence for more than a few hours. Cerebral tumour is the usual lesion causing aphasia of gradual onset, and is perhaps the only known cause of isolated "word deafness" and of "voluble jargon aphasia," for it is the only conceivable lesion which can undercut and, therefore, isolate the temporal convolutions without otherwise interfering with their function. Inflammatory conditions of the brain seem seldom to occur as factors of aphasia. One may meet with transient symptoms of this order in connection with the various forms of meningitis, and also in encephalitis, but I have never seen any permanent form of aphasia resulting either from polioencephalitis or from lethargic encephalitis. Traumatic lesions of the speech area which are common in times of war are often from their succinct nature productive of most valuable cases of aphasia from the point of view of the analysis of speech function. Aphasia may occur as a transient phenomenon in epilepsy and in migraine, of which disease it is a well-known sign. It may also be met with in uræmia, in the "nervous" attacks of high arterial pressure without albuminuria, and in the "congestive" attacks of general paralysis of the insane.

PHYSIOLOGICAL CONSIDERATIONS.—A useful conception of the physiological mechanism of speech is most easily arrived at by a consideration of the way in which speech is acquired by the infant in the process of its development. Within a short time after birth the child begins to recognise the nature and uses of some of the objects in the world around it, and to express its simple conscious process by gestures, and it early appreciates the "gesture language" of those around it. The "mimesis," or gesture language, thus early impressed and expressed, remains throughout life the most stable, the least vulnerable, and the longest lasting of the methods of receiving and communicating ideas. Even when the function of speech is reduced to annihilation by lesions of the speech area, mimetic language remains, and it only disappears when intelligence or consciousness is reduced to a low ebb. Long before it is able to utter any articulate sound, the infant learns to connect certain sounds which it hears with certain objects and with certain events, and the memories of these auditory patterns first implanted serve by far the most important function in the processes and expressions of thought throughout life. Whereas we rely upon our visual memories for our remembrance and intelligence in general matters almost exclusively, yet as regards speech we rely upon auditory memories to a very large extent, and of course those who have never learned to read do so exclusively. The process of recall, both in silent thought and in speaking, is the revival of auditory patterns. We are, therefore, strong "visuals" as regards general

memory, but strong "auditives," as regards speech memory, and the relative strength of the two functions varies somewhat in individuals, according to personal idiosyncrasy and to education, and this individual variation is sometimes apparent in the phenomena of aphasia. From the original connection with hearing, the memories of speech patterns come to be located in that part of the brain associated with the auditory function—in and around the temporal lobe. Later, guided by the auditory memories, the child begins to express himself in articulate speech and he does so by the revival of auditory memories.

It is essential to bear in mind that all motor processes have been evolved from reflex actions, and that all living motion is sensory-originated, sense guided and sense governed, and that a motor process of itself has no proved conscious concomitant, our consciousness of motor processes being the consciousness of the sensations which accompany the movement, or which result from the movement. In speaking, for example, we gain the knowledge that we have spoken what we wished correctly by the immediate backlash of our voices sounding in our ears, and also by the sensation of correct articulation which reaches the sensorium from the executive organs. The knowledge of correct execution so gained fortifies and increases the functional stability of the speech area, and is of immense importance in the speech function. If it be absent owing to a lesion isolating the speech area on the incoming side, speech degenerates into a jargon and soon becomes impossible; just as in tabes the walking becomes irregular from loss of the muscular sense conveyed in the posterior columns, and ultimately standing becomes impossible.

When at a considerably later and less impressionable age the child learns to read and to write, certain visual patterns (letters, words, sentences) become connected with certain objects and ideas, and become linked on to the already well-established auditory memories of speech. The meaning of the visual symbols is learned by the child from the meaning of the word or pattern spoken, which he already knows well, and the already developed auditory speech function serves as the instructor of the visual speech function, and throughout life remains the more potent, more dominant and less vulnerable function of the two.

Later still, in learning to write, the child relies upon his visual memories, and as his knowledge of correct execution in writing is largely visual and only in minor degree common sensory from the movements of the hand in writing, it follows that the function of exteriorising speech by writing becomes intimately connected with and a part of the visual speech function, and is usually depressed or lost with the visual speech function as the result of disease. It will thus be seen that there are not separate regions of the speech area in which the auditory memories of language and the execution of spoken speech on the one hand, and the visual memories of language and the execution of written language on the other hand, are represented, but that there are four functions intimately coupled in pairs, which have their seat in the same anatomical substratum. Supposing that in later years the child learns a language in addition to his mother tongue, there is no fresh organisation of speech centres, but he impresses a further function—another set of speech patterns—upon his already trained speech mechanism, but this added function will never be so deeply impressed as that of the mother tongue, and

when the speech region of the brain is damaged the less impressed function will tend to be lost first and most.

It is a general principle that when the speech area is damaged the speech function becomes depressed as a whole, with the result that function is lost in order of its depth of impression. For example, with any lesion of the speech area which does not conspicuously involve the incoming and outgoing paths the first signs likely to appear are depression or loss of the visual speech function, for this is much less deeply impressed than is the auditory speech function. This loss will be greatest upon the executive side and less upon the receptive side, for the receptive side is always more deeply impressed and functionally more stable. With an increasing lesion, as more and more of the speech area is involved, the auditory speech function will be involved first upon the executive side, and last and least upon the receptive side. This principle first came into prominence many years ago with the general recognition of the clinical fact that the greater number of the cases of Broca's "motor aphasia," even though the lesion was subsequently shown to be confined to the base of the third pre-frontal gyrus and neighbouring part of the insula, showed for a time after the occurrence of the lesion, relative or complete inability to recognise written language—in other words, they were word-blind, although intelligence was good and there was no lesion in the region of the angular gyrus to account for the loss of visual speech. And it was emphasised by the many reported cases in which complete inability to speak was caused by a lesion confined to the temporal lobe.

DIASCHISIS.—Von Monakow, who still held that the visual and auditory, and the receptive and executive speech functions were separately represented in the cerebral cortex, gave this name to the dropping out of function in terms of the depth of impression of function. The term actually means "breaking of the synapses," and he applied the principle of diaschisis to the brain generally to explain the local loss of function in regions far distant from the lesion, but functionally connected with the damaged region. At the present day the term is used with a functional meaning only, for it is obvious that it can have no anatomical meaning.

The loss of the less deeply impressed elements of the speech function in regular order is sometimes well exemplified in aphasic persons who are facile in many languages. This principle is no more than a restatement of the well-known fact that as age advances, the nervous system is less impressionable and at a lower functional level, and, therefore, that memories of recent events are much less vivid, more easily forgotten and much more difficult of recall, than are memories of long ago.

Symptoms.—So far the varying degrees of word-blindness, word-deafness, aphasia and agraphia from lesions of the speech area, have been attributed in this account of the subject to sub-cortical lesions of the incoming and outgoing paths on the one hand, and functional depression of the speech mechanism as a whole on the other hand. It remains to make some attempt to elucidate the functions of the cortex of the speech area, or rather to suggest what defects may result when this cortex is damaged. It will be obvious that lesions confined to the cortex of this area alone are almost unknown.

Small lesions of the convolutions of the size of a sixpenny piece seem to produce no defects at all, and this is perhaps true of all the regions of the cortex of the brain. There can be, therefore, no narrow localisation of

function, and there must be capacity for compensation for such small lesions in the surrounding undamaged cortex. With larger lesions of the cortex, and in proportion to their extent, mutilation of the patterns of speech, slowness of utterance, inability to find the words (inability to recall), especially nominals, and above all isolated nominals, and finally confusion of speech intelligence occur, in that order.

In the mutilated speech of the aphasic may be sometimes noticed stammering, and I have seen two cases in which the end result after great improvement was indistinguishable from ordinary stammering even as to the words, thus constituting a jargon utterance. This condition is at once distinguishable from true jargon aphasia, since the former is slow and halting whereas the latter is facile and voluble. Misplacement of words and the use of wrong words is common and is called "paraphasia." A tendency to repeat a word once pronounced is sometimes present and bears the name "echolalia." The same faults occur also in writing, as faulty spelling, misplacement of letters and words, wrong words, "paragraphia" and "echo-graphia." Dr. Head has classified those defects which may be due to the cortical lesion as (a) Verbal and Syntactical, which have to do with the faulty pattern of speech, (b) Nominal, which are the difficulties of recall, and (c) Semantic, which are the troubles of confused speech intelligence; and he suggests that the first of these groups is associated more particularly with damage to the anterior half of the speech cortex, and the second and third groups with damage to the posterior half. It is quite certain that these three groups make their appearance in this order with an increasingly extensive lesion of the speech area. Much defect of general intelligence always accompanies severe damage to the speech area, and this will be readily understood from the very large rôle which speech patterns play in the working of thought. Difficulty in the recall of words and speech patterns, which has been termed "verbal amnesia" or "nominal deficiency," is a characteristic feature of lesion of the speech area, and as a purely functional defect is a common experience in all of us when we are at a loss for a word or a name, or fail to express our meaning clearly, especially when the physiological level of the speech function is depressed by stage fright, or lack of confidence, or other embarrassment in consciousness. This difficulty is greatest with spontaneous revival than with recall, which is "kicked up" by direct sensory stimulation. For example, an aphasic person who is unable spontaneously to utter a word, may repeat the word at once when it is spoken to him, when he sees it in writing, or when the corresponding object is shown to him. It is greater with single words, especially with nominals, and less with sentences. For example, a patient was asked to say "No," and after vain endeavours he ended by saying, "I can't say 'No,' sir." Here the impossible word was brought up in the run of the pattern. It is important in this connection to bear in mind that we do not speak in the letters of the alphabet, nor in the words of our dictionary, but in a running pattern of sound. The pattern or context provides the meaning, while the individual words are negligible and have no meaning unless we put them into another pattern by parsing them. During the long ages in which man spoke before the invention of writing, he used the running pattern of sound, not yet arbitrarily made up of letters and divided into separate words. From this will be explained why an aphasic will often gather something from a sentence or speech pattern when he

accepts no meaning from a single word, and why he may be able to put forth a proposition in the form of a sentence when he cannot utter any one of the words composing it singly. The power of the pattern in aiding revival is very great both from sequence rhythm and musical quality. As examples, an aphasic who has no utterance spontaneously is told to count with his interlocutor. The interlocutor begins counting, the aphasic joins in. The interlocutor then stops, but the aphasic continues counting, carried by the sequence rhythm. Again, a patient under my care totally aphasic from a puerperal thrombosis, who had no speech acceptance and no speech utterance, was observed to join in with a hymn that was being sung in the ward and to sing lustily with only the slightest mutilation of the pattern. On the next occasion that this hymn was sung, orders were given for the singing to stop suddenly in the middle of a verse, when the aphasic patient went on singing alone, and the music continuing, she finished the hymn. This case clearly proves that the condition was not one of destruction of centres in which speech reception and speech exteriorisation were concerned, but it was one in which the speech function as a whole was depressed beyond power of physiological action from a lesion of the speech area, but yet could be roused into a condition of relatively high activity by the emotional element of rhythm and music. Dr. Hughlings Jackson reported a case of the inmate of an infirmary who had been bedridden and without utterance for years by reason of a Sylvian thrombosis, who waking in the night to find his ward in flames was so stirred by the prospect of being immediately roasted, that he shouted "Fire! fire!" with such vehemence as to summon the assistance by which he and his fellow inmates were saved.

The same phenomena are observed upon the acceptive side of speech as have been just exemplified upon the expressive side. Dr. Head has shown that patients who seemed entirely unacceptive of spoken and written speech could still match an object with its name, or a colour with its name, from among a set of objects, colours and names presented simultaneously. Here the sensory stimulus of both the object and its printed name served to rouse the speech function into some degree of recognition.

The confusional or semantic defects of speech function are met with in extensive damage to the speech area, and are usual as immediate and transient phenomena in all suddenly occurring lesions of the speech area. There is general mental dullness, with varying degrees, usually severe, of depression of speech function, and much confusion, both on the acceptive and expressive side, when any of these functions remain, and the results of the examination of the speech faculty are apt to vary very much from moment to moment, for attention is very difficult to hold and the patient is easily fatigued and bored. Severe degrees of this form of defect may be associated with inability to recognise objects—"object-blindness," and with loss of ability to convey ideas by gesture—"amimia."

Prognosis.—In attempting to estimate the degree of recovery which is likely to occur in cases of aphasia, it is necessary first to bear in mind that sudden cerebral injury is apt at first, by the process which has here been described as functional depression or "diaschisis," to cause very wide loss of function, though the lesion may not be very extensive. A total aphasia, for example, is often the immediate result of lesion of moderate size. Such phenomena last usually not longer than a week, and until they have passed off

it is impossible to make a definite statement, either as to the extent of the lesion or the likely degree of recovery. Speech may be regained by two entirely separate processes—either by recovery of function in partly damaged and functionally depressed areas, or by compensatory activity in the potential speech area of the undamaged hemisphere. The possible recovery of function will depend upon the nature of the lesion and upon its extent. It will be greater when a lesion may be judged to be one of pressure rather than of actual destruction, if such pressure be removable, as in sub-dural hæmorrhage, abscess and gumma, and least when widely spread arterial disease and a failing heart suggest that the lesion is a thrombosis, and when an irremovable tumour is present. The greater the extent of the lesion if it be presumably from vascular occlusion, as judged by the associated signs, paralysis, anesthesia and hemianopia, the less is the chance for functional restitution, as there is then little hope of any useful restoration of the circulation through collateral vessels. When the lesion is deeply seated, as, for example, a lesion of the left internal capsule, producing dysarthria, the probability of recovery is great, as there is an alternate path for speech execution, by way of the corpus callosum and right pyramidal path. The capacity of transference of function from a damaged speech area to the corresponding region in the other hemisphere, varies so much in individual cases that few definite statements can be made with regard to prognosis, but as a rule the younger the patient is, the more certainly does this compensation occur. In children under the age of six years, unilateral lesions produce no permanent speech defects, provided sufficient intelligence remains, but even to this rule some important striking exceptions have been recorded. When adult life is reached, transference seems to occur but little, yet in a few recorded instances destruction of the posterior half of the speech area has been followed by an almost complete restoration of speech function.

Treatment of Speech Defects.—A careful and patient system of re-education in speech, such as is used in teaching mentally deficient children, is often of great value in all forms of speech defect. From the amount of labour that the teacher has to expend for very little progress made, this treatment is not often given a fair trial. A fair degree of intelligence must be present, and care must be taken that the lessons are not prolonged to the production of the boredom, with accompanying inattention and confusion, which occurs so readily in aphasic patients. The utterance of a simple vowel sound should first be taught, then that of the several vowel sounds, and afterwards that of consonants and their combinations, and the patient should be directed while learning to watch the movements of the lips, etc., of the teacher. The simultaneous presentation of an object with its spoken and written name is often helpful in stimulating the remains of speech function into activity. An intelligent patient soon comes to recognise under such tuition that he has no paralysis of the articulatory mechanism.

TESTAMENTARY CAPACITY.—No rule can be laid down as to the capacity of a person suffering from speech defects to exercise civil rights and to make a will, and each case must be judged upon its own merits. The first and all-important consideration is the degree of intelligence, and when this is good it is essential for such capacity that there should be some mode of cognition and of expression left. Pure word-blindness and the extremely rare condi-

tion of pure word-deafness do not interfere with the exercise of civil rights, for the patient can understand what he hears in the first case, and what he reads in the second, and in both conditions can express himself both in speech and writing. In cases of pure aphasia and pure agraphia there is complete civil capacity, but when, as usually happens, the two conditions co-exist, though intelligence and the receptive side of speech may be but little impaired, yet the expressive side of speech is reduced to gesture, and extreme difficulty may be met in ascertaining the patient's wishes. Auditory amnesia, and combined auditory and visual amnesia, and confusional defects, except in the slightest forms, interfere seriously with testamentary capacity and with capacity for exercising civil rights. In such cases there is great loss both on the acceptive and on the expressive sides of speech, with confusion of memory and impairment of intelligence. Most satisfactory results have, however, many times been brought about in apparently hopeless cases by careful, sympathetic and repeated procedures, in which the properties to be bequeathed and the likely legatees are assembled before the patient, thus allowing the testator to match the gift with the recipient. The proceedings should be conducted in the presence and under the direction of a physician thoroughly conversant with the subject of aphasia. All concerned should bear two points in mind, the one being that the wishes of the legator must be paramount, and the other that an obviously just will is most difficult to upset in a court of law.

THE METHOD OF EXAMINATION of patients suffering with speech defects should be in accordance with some definite scheme so drawn up as to test each function of the complex physiological process of speech.

The following scheme is convenient: (1) Is the patient right- or left-handed, and, if the latter, did he write with the right hand? (2) What was the state of education as regards reading, writing and foreign tongues? (3) Does he understand the nature and uses of objects, and can he understand pantomime and gesture, or express his wants thereby? (4) Is he deaf? If so, to what extent, and on one or both sides? (5) Can he recognise ordinary sounds and noises? (6) Can he comprehend language spoken? If so, does he at once attempt to answer a question? (7) Is spontaneous speech good? If not, to what extent and in what manner is it impaired? Does he make use of wrong words, recurring utterances, or jargon? (8) Can he repeat words uttered in his hearing? (9) Is the sight good or bad, is there hemianopia, or papilloedema? (10) Does he recognise written or printed speech and obey a written command? If not, does he recognise single words, letters, or numerals? (11) Can he write spontaneously? What mistakes occur in writing? Is there paraphasia? Can he read his own writing some time after he has written it? (12) Can he copy written words, or from print into writing? Can he write numerals or perform simple mathematical calculations? (13) Can he read aloud? (14) Can he name at sight words, letters, numerals and common objects? (15) Can he write from dictation? (16) Can he match an object with its name, spoken or written, when a series of objects and names are simultaneously presented? (17) Any other tests, emotional, rhythmical, or musical, which may raise the physiological level of the speech centres. (18) Any other means of proving in what way he can receive and express ideas.

IMPEDIMENTS OF SPEECH

1. STAMMERING OR STUTTERING.—A spasmodic defect of articulation leading to a sudden check in the utterance or words, or to a rapid repetition of the consonantal sounds in connection with which the difficulty arises. To the trouble with articulation are often added spasmodic movements of the face and head, or indeed of any part of the anatomy.

Except in the rarest instances this condition is not associated with any structural changes in the nervous system nor in the organs of articulation, but it has been observed as the end result of a lesion of the speech area. The disorder seems to consist in a lowering of the functional stability of the executive speech mechanism by a physiological embarrassment in consciousness. It is begotten of shyness and self-consciousness. It is never congenital, nor met with in early infancy, but arises at the age when shyness and self-consciousness trouble youth most. It is infinitely commoner in boys than in girls, for the latter are much less liable to self-consciousness. The stammerer never stammers in the speech of thought, nor when talking aloud to himself alone, nor at any time when singing, for in the two former cases the embarrassment of self-consciousness is absent, and in the last case the element of rhythm and music greatly increases the stability and confidence of the function. It not uncommonly appears in conditions of debility, and especially after measles and diphtheria. It has a frequent origin in sudden fright, and during the Great War thousands of soldiers who had never stammered before were thus afflicted. It is the historical utterance of fright and of those who find themselves suddenly "flagrante delicto." In rebellious cases the element of self-consciousness seems to disappear, while the stammer persists as an ineradicable habit, and it is remarkable how many sufferers of this class have strong aspirations towards public speaking.

In articulate speech three muscular mechanisms are concerned—(1) the respiratory mechanism for supplying the blast of air, (2) the larynx for producing the voice, and (3) the muscles of the lips, tongue, jaw, and palate for articulation. For distinct speech there must be absolute co-ordination of these mechanisms one with another. Consonants are in nearly all cases the source of the difficulty in stammering, and while these are all buccal sounds, yet some begin with a laryngeal sound, while others are purely buccal. The former are termed "voiced consonants," and are B, W, V, Zh, Z, Th (as in "thus"), D, L, R, G, Y; and the latter "voiceless consonants," and are P, F, Th (as in "thin"), S, Sh, T, K; while N, M, and Ng terminal are "voiced nasal resonants." If one articulates these consonants it becomes at once clear that it is the presence of the initial laryngeal element or "voicing" which makes the difference between B, V, Z, D, G, and P, F, S, T, K, respectively.

A careful attention to the manner in which the letter sounds are produced is absolutely essential in the investigation and treatment of stammering. The difficulty occurs most commonly with the explosive consonants, P, B, T, D, G, K, and nearly always where these occur as initial letters—that is, in starting the articulatory mechanism; and to avoid this difficulty which arises after every pause, most stammerers speak in a rapid monotonous

fashion. The fault chiefly lies in the direction of energy to articulation rather than to phonation. The patient held up by his stammer usually remains silent, but occasionally, having produced the first sound, he continues to repeat it—the reduplication stammer which has been the origin for the names “stammer” or “stutter” by which the malady is known.

Often the patient uses a trick or contortion to prevent the stutter or to relieve the feeling of nervous tension and embarrassment in consciousness which the defect causes, and these tend to become engrafted on him, as (1) associated sounds—whooping, grunting, crowing, etc.; (2) habit spasms—contortions of the face, limbs, or body, which sometimes take a complicated form and exactly resemble the co-ordinated forms of tic.

Prognosis.—The majority of the cases tend to a spontaneous cure, and recovery is hastened in all cases by systematic treatment. In every class of case the results of treatment may come slowly at first, but perseverance will in almost every case bring success.

Treatment.—Attention should be paid to conditions of general health, and to the mental well-being and satisfaction of the child, with plenty of scope for pleasure and satisfying occupation. Subjects of a highly nervous and sensitive temperament are often much benefited by a course of strychnine, bromide and glycerophosphates, and also by aspirin—which should always be employed in a stammering child who is suspected of being rheumatic.

The patient should be removed as far as possible from causes tending to increase his self-consciousness and from the ridiculing of his defect, and he should have daily speaking exercises. It is well for him to speak, read, or recite in a large room alone, loudly, slowly and distinctly. The following system for such exercises is useful: (1) The chest must be kept well filled with air. This most important point is often most difficult to the patient. (2) He must speak slowly, with a full resonant voice. (3) When he comes to the word on which he tends to stutter, he should raise his voice and direct his energies to vocalisation, and not to articulation. If the difficulty be over a voiced consonant, he must be directed to voice it firmly. If the consonant over which he stumbles be a voiceless one, attention must be directed to the vocalisation of the subsequent vowel sound; for instance, in “pat” he must attempt to vocalise the “at,” and he will find little difficulty in prefixing “p” as the syllable is uttered. (4) Gymnastic and singing exercises are valuable additions to treatment. Should associated movements be present, the speaking exercises may be carried on in front of a mirror, so that the patient may see these himself and endeavour to suppress them.

The development of confidence and self-reliance is everything in the treatment of stammering. The skilled teacher first gains the liking, respect, and submission of his patient. He then assures him that his defect will disappear, and that he can cure himself, and demonstrates to him by correcting the faults that he can speak normally. When stammering arises suddenly as the result of shock, as in the Great War cases, it should be treated as is aphonia and other hysterical paralyses, by demonstrating to the patient that his trouble is superable. I have seen a queue of such stammerers who were waiting for treatment cured by the emergence of the worst of their number from the “wizard’s den” proclaiming his recovery.

2. **LALLING**.—A defect due to want of precision in the action of the oral articulatory mechanism. It characterises the speech of many children before the art of articulation is completely learnt. It is only a persistent condition in some cases of defective intelligence.

3. **LISPING**.—A defect due to the indistinct enunciation of certain consonants, or to the substitution of wrong consonants. It usually occurs in connection with the sounds of Th, R, and S, which change to V, L, and Th respectively. The condition, which is almost usual in infants learning to speak, is due to faulty articulation, and may become a habit, in which case the subject has probably a bad "ear" for sound. Defective conformity of the mouth may cause it; for example, a "tongue tied" person can never pronounce the English R correctly.

4. **IDIOGLOSSIA**.—A condition in which from the first moments of learning to speak, a child uses wrong consonants, or rather he tends to substitute three or four consonants for the whole series. Very slight degrees of idioglossia are common in little children, whose early speech is intelligible only to their nannies. In marked cases the child comes to speak a language entirely its own. The following admirable illustration is given by Dr. Colman from one of his patients, who thus repeated the Lord's Prayer:

"Ouë Tahde na ah in edde, anno de Di nay, I tidde tah, I du de di on eet a te e edde, te ut te da ouë dade ded, e didde ouë tetedde a ne abdin to te tetedde adase ut, ne no te tetate, ninne utte enu, to I ah te ninne, pouë e dordy to edde e edde. Amé." This patient substituted "t," "d," or "n" for most of the other consonants.

The course of time and education removes the defects of lisping, lalling, and idioglossia, and the prognosis in all these conditions is invariably good.

Any deformity of the articulatory organs should be remedied if possible.

5. **APHTHONGIA**.—A condition in which the attempt to speak sets up severe spasms in the muscles of articulation, chiefly in the tongue. Nothing is known of the pathology of this rare disease, which from the descriptions (for I have never seen an example) may be akin to myotonia, tetany, or occupation cramp.

JAMES COLLIER.

APRAXIA

Definition.—A disorder of cerebral function, characterised by inability to perform certain familiar purposive movements, in the absence of motor and sensory paralysis and ataxia. This disorder does not depend upon defective perception (agnosia) nor upon general reduction of intelligence.

Ætiology.—Apraxia may result from both general and local diseases of the brain. It may be met with in general paralysis of the insane, in cerebral sclerosis and in several forms of dementia, and in paralytic chorea. It occurs in its purest form from local lesions of the brain, and may then be confined to one region of the body. It may result from lesions of the posterior part of the prefrontal area of the left side, the so-called "motor or verbal" aphasia and agraphia being good examples of apraxia of speech, and lesions in this region may also cause right-sided apraxia of the limbs. Lesions of the anterior half of the corpus callosum have been associated with conspicuous apraxia, as have also bilateral lesions in the posterior parts of

the hemispheres. In the latter cases, the apraxia is likely to be associated with some degree of lack of recognition of an object, and of its uses (agnosia), and this causes apraxia from a loss of correct comprehension of the act required. Von Monakow is of opinion that lesions of the supramarginal gyrus cause apraxia. Apraxia is sometimes met with in cases of hemiplegia in which, notwithstanding the complete recovery of motor and sensory paralysis, the performance of familiar acts—from the highest skilled movements, such as the fingering of the pianoforte or of the violin, or the use of his tools by a craftsman, to the simplest act—may be no longer possible. Apraxia may be summarised as an inability to convert a correct idea of an action into the required movement. The features of the condition may be well demonstrated by the consideration of left-sided hemiapraxia. There is neither loss of power nor loss of sensibility in the left upper extremity. When such a patient is asked to perform some familiar act with the right hand, he at once does so correctly, but when ordered to perform the same act with the left hand he is unable to do so. Either he makes aimless wandering movements with the left hand, or he may succeed in making movements somewhat resembling those required of him, with much slowness and clumsiness. Sometimes he may perform some act which is entirely different to that required of him, and this phenomenon is called parapraxia. When the apraxia is partial, the patient may be able to perform some acts and not others, his inability usually, but not always, increasing with the complexity of the act required. Or he may be able sometimes to perform an act in which he commonly fails. Not infrequently such a patient, wearied with the unsuccessful attempts of his left hand, will abruptly perform the act correctly with his right hand, to get rid of it. And he will define his defect by saying, "I know quite well what you want me to do, but I cannot do it." Spontaneous volitional movement is similarly affected, and this leads invariably to a marked loss of initiative in the use of the affected limb—the patient will not try to use it. The apraxic patient is often to an astonishing degree unaware of his disability, and frequently becomes conscious of it for the first time when it is pointed out to him by another person. For instance, a patient who had been skilled in boxing, was affected with apraxia of the left upper limb. When asked by his physician to stand up and spar with him, he at once arose with evidence of confidence and pleasure, and placing his feet, body and right arm in the correct position, commenced to box with his left upper extremity swinging helplessly from the shoulder. He then for the first time became aware of his disability.

Diagnosis.—Apraxia may be confused with astereognosis, with agnosia and with cortical ataxia. A correct conception of the nature of the two former conditions will exclude the possibility of error. In cortical ataxia the patient obeys the word of command at once and succeeds more or less with the act required, the defect being clumsiness of execution. The clinical examination of patients for apraxia must include—(1) the general psychical condition as regards attention, memory and reasoning; (2) an inspection of sensory appreciation for defects of simple perception in the regions of smell, sight, hearing, taste, cutaneous sensibility and muscular sense; defects of recognition of sensory impressions in these regions (agnosia); defects of memory; and (3) an examination of executive power for any defects in the movements determined by visual, auditory, tactile and kinæsthetic

stimuli. What response does the patient make to objects held in front of him or to gestures made to him? Can he imitate movements? Can he when requested make simple and purposive movements, with and without the objects in his hands? When given an object, how does he hold it and use it?

AGNOSIA

In certain conditions of cerebral disease, it is found that each and all of the sensory organs, when called into play, may fail to arouse an intelligent perception of the object exciting them. This inability to recognise the import of a sensory stimulus is called agnosia. Those patients who present apraxia and agnosia, often show other interesting phenomena which are of importance; these are (1) inattention, (2) defective capacity for retaining recent impressions, (3) lack of initiative, and (4) perseveration. Perseveration consists in the repetition of an already executed movement when and only when the patient desires to make a fresh movement. A patient of Pick's, for example, blew out a candle and then blew upon all objects presented to him during the next few minutes. The relation of apraxia and agnosia among the disorders that impair voluntary movement is well shown by a scheme which, passing along the cerebral sensory-motor path from sensory to motor, sets down in order these clinical conditions. The following scheme is from Kinnier Wilson's monograph:

(1) Cortical blindness, cortical deafness, cortical sensory paralysis,—loss of visual, auditory and cutaneous, etc., ingoing impulses. (2) Cerebral ataxia: loss of afferent kinæsthetic impressions, resulting in erroneous estimation of range of movement, power, etc. (3) Mind palsy: incapacity of movement from loss of kinæsthetic memories for complex movements. (4) Agnosia: Conservation of sensation, but failure of recognition; loss of sensory memories. (5) Ideational agnosia: loss of the spatial associations and interconnections which make up the idea of an object from its component ideas. (6) Ideational apraxia: defective synthesis of the ideational components in a movement-complex. (7) Motor apraxia: intactness of the cortico-muscular apparatus, but inability to translate a normally produced idea of movement into its corresponding movement-form. (8) Cortical motor paralysis.

CEREBRAL DIPLEGIA

Synonyms.—Congenital Spastic Paralysis; Lobar Atrophic Sclerosis.

Definition.—A series of clinical conditions, dependent, not upon gross local lesions of the higher nervous system, but upon lack of, or imperfect development, or degeneration of the nerve cells of the cerebral cortex, basal ganglia or cerebellum. This agenesis of nerve cells may affect those cells of the pyramidal system which are the latest to develop before birth, namely those for the supply of the lower extremities and the resulting clinical condition is cerebral spastic paraplegia or Little's disease, or all the cells of the pyramidal system may be affected, producing generalised spastic rigidity.

Again, the higher regions of the cortex may be affected, and the result is congenital idiocy. Similar affection of the cells of the basal ganglia result in congenital bilateral athetosis, and congenital chorea. When the cerebellum is involved, congenital cerebellar ataxy results. Further, there may be any combination of the above conditions. Lastly the whole of the cells of the entire nervous system may be progressively affected, as in amaurotic family idiocy.

Ætiology.—The malady may be apparent at the time of birth, as the child may be born with contractures present. More often, the signs of deficient or perverse movement, or of mental deficiency, appear during the first year of life, as the signs of cerebral activity commence to be exteriorised. In other and rarer cases, the degeneration of the nerve-cells seems to be truly post-natal in onset, as in amaurotic family idiocy. In most cases no heredity can be traced, but sometimes several children of the same mother may be affected, and direct heredity has been known. Amaurotic family idiocy is always familial, and is almost, but not quite, limited to the Hebrew race.

Abnormalities of birth are remarkably frequent. Premature birth, precipitate birth, prolonged birth from uterine inertia rather than from dystocia, and asphyxia neonatorum are all common, and it is possible that prematurity and asphyxia neonatorum may be definite causal factors in some of the cases. Maternal ill-health during pregnancy has occurred in a few cases, but it is usually conspicuous by its absence.

If we regard the brain from the time of its earliest stages of development as a field sown with seeds (neuroblasts), which germinate at different periods of foetal life, and the germination is not even complete at the time of birth, the germination of all the elements in due time and their complete development being necessary for the formation of the perfect brain, then we may liken the cause of diplegia to some baneful influence, such as a frost, which acting at a particular time, may spare those seedlings which are well developed and able to withstand it, and those seeds as yet not germinated, but which causes havoc among the tender germinating seedlings, either to their death or severe maiming. In some cases, as, for example, in Little's disease, the neuroblasts thus affected may, after a period of retarded development, ultimately become strong plants and complete their development. The nature of this baneful influence is mysterious. It may be of the nature of a toxin, or of an internal secretory deprivation. It is of interest, that in the highest degrees of cerebral agenesis, anencephaly, pituitary abnormalities seem to be constant.

Pathology.—The essential histology of the affected regions is that of non-development, paucity in numbers and degeneration of the nerve cells, with corresponding absence, poor development, degeneration or a combination of these states, of the tracts which spring therefrom. The pyramidal tract, for example, may be found absent throughout, or it may reach to the medulla, or to the cervical region only, and so show at what period development was arrested. The changes in the nerve cells are followed by secondary gliosis, and the affected regions are firmer and smaller than normal. The final result is termed atrophic sclerosis, which is greater in degree, the more severe the case, and the longer life has been preserved. The atrophic sclerosis may affect the whole surface of the hemispheres equally, but more often certain regions are profoundly affected, while others escape relatively or completely ;

but the distribution is always symmetrical upon the two hemispheres. In generalised rigidity with idiocy, the whole of the hemispheres may be affected. Where motor symptoms are slight and mental reduction profound, the frontal and occipital regions are predominantly affected. In paraplegic rigidity, the atrophy is confined to the paracentral lobes and neighbouring convolutions upon the convexity of each hemisphere, a lozenge-shaped depression of remarkable appearance occupying the summit of the cerebral vertex. In the atrophied region, the convolutions are unduly hard to the touch. They stand away from one another and are smaller than are normal convolutions, and the sulci between them are widened. Their surfaces often present a worm-eaten and faceted appearance. Each convolution is ridge-like, and does not preserve its level, now sinking and now rising. This irregular form of the convolutions, with wide, separating sulci, gives the brain a characteristic appearance, like that of a walnut kernel. Affection of the cerebellum causes a similar shrinking and hardening. Sections of the brain stem and spinal cord may show a complete, or relative, absence of the pyramidal tracts.

Symptoms.—The clinical picture of the several forms of cerebral diplegia presents a combination in varying degrees of certain characteristic symptoms, always bilaterally distributed, though sometimes more severe on one side than on the other. These symptoms are: muscular rigidity, paresis, perverse movements, contractures and increased deep reflexes. Mental deficiency, optic atrophy, ocular palsy, ataxy, and bulbar paralysis are other important symptoms. The signs of the disease become obvious during the first year of life or soon after. In severe cases, soon after birth, the nurse, in washing the child, is the first to notice the stiffness of the limbs, or the regular assumption of a curious bodily attitude. Otherwise, the abnormalities may not be obtrusive, until the child should sit up or learn to get about, when weakness, rigidity, perverse movements and pes cavus may call attention, or backwardness in learning to walk and to talk, and mental deficiency may first suggest that there is something wrong with the child. The following are the common types of the disease, but it must be remembered that any combination of, or transition between, the types may be met with. Amaurotic family idiocy has certain peculiar features which necessitate a separate description for this malady:

1. *Generalised rigidity; general congenital spastic paralysis.*—There is extensive defect of the pyramidal system. The rigidity and weakness affect the whole of the musculature.

2. *Paraplegic rigidity; congenital spastic paraplegia; Little's disease.*—The pyramidal deficiency is confined to that supplying the lower part of the trunk and lower limbs.

3. *Congenital bilateral athetosis and congenital chorea.*—The agenesia affects the cells of the basal ganglia, with the appearance of irregularity of movement, and of spontaneous involuntary movements, which may be of an athetotic, choreic or irregular type. A certain variable degree of general rigidity is present in these cases.

4. *Congenital cerebellar ataxy.*—The agenesia affects the cerebellum with the appearance of cerebellar ataxy. In this type, the limbs are flaccid, and in mixed cerebral and cerebellar types there is a tendency to hypotonicity of the muscles, instead of rigidity.

5. *Congenital idiocy; restless idiocy*.—The agenesis affects those parts of the brain concerned with the higher functions. These children are emotionless, restless and unteachable. The skull often shows frontal or occipital microcephaly.

6. *Microcephalic idiocy*—where the agenesis is of the whole brain and the skull very small.

7. *Amaurotic family idiocy*.

PARESIS AND RIGIDITY.—Except in severe cases, in which the weakness amounts to complete paralysis, there is more rigidity than weakness, and it is often astonishing that there should be so much power in the presence of such a degree of rigidity. The lower extremities are generally the most affected, the upper to a less degree, and the facial region still less. Movement is slow and clumsy and resembles that of the tardigrade animals, and spontaneous involuntary movements are often present in the limbs. Contractures accompany the rigidity, and if walking is possible the gait is digitigrade from contraction of the calf muscles, the knees are flexed from contracture of the hamstrings, the thighs are rotated inwards, and the knees pressed together, rubbing against one another. More severe adductor spasm gives rise to the cross-legged progression. The rigidity and contractures, when severe, may give rise to peculiar attitudes and deformities. A mask-like expression of face, with wide palpebral apertures and large open mouth, is not infrequent. Slobbering is very common. The head may be rigidly retracted, but more commonly the chin is pressed down upon the chest. The spinal column generally shows some deformity in the way of kyphosis, lordosis or scoliosis, and pes cavus or equino-varus is the rule.

PERVERSE MOVEMENTS.—Under this heading must be grouped the very constant maladroitness of voluntary movement, the facial over-action and grimacing in speech and in mimetic expression, choreic movements, athetotic movements and intention tremor. Common sensation and the muscular sense are unimpaired. The sphincters are unaffected. The deep reflexes are increased, but are often difficult to obtain when rigidity is very marked. The trunk reflexes are often absent, the plantar reflexes usually are extensor in type. Since the growth of the skull follows and conforms with that of the brain, cranial abnormalities are common. There may be microcephaly, asymmetry and flattening in the region of the central convolutions, or a furrow corresponding with the interhemispheric fissure, or frontal, or occipital smallness and flattening. Every degree of mental reduction may be met with, from precocity and slight mental dullness to complete amentia. But this by no means corresponds with the severity of the bodily symptoms, for the mental defect is often most severe, when the bodily symptoms are slight, and conversely. In some cases, very high intelligence persists, when there is utter uselessness of the limbs, and when speech is hardly intelligible. Primary optic atrophy occurs in a small number of cases. Inequality of the pupils and slowness of light reaction are not uncommon. Nystagmus is often met with. Convergent strabismus occurs in about one-third of the cases. Convulsive attacks are of common occurrence, and in about one-eighth of the cases epilepsy becomes established.

Diagnosis.—When the symptoms are well marked, the diagnosis presents little difficulty, since the disease dates mostly from birth, or is discovered during the first year of life. Paraplegic rigidity may possibly be confused

with other forms of paraplegia, and, especially, with that resulting from spinal caries. Certain cases of pontine tumour may closely resemble generalised rigidity. The occurrence of such conditions during the first two years of life is, however, very rare.

Prognosis.—In many cases of generalised rigidity, and in all cases of paraplegic rigidity, there is a tendency to slow amelioration of the rigidity, an increase of voluntary power and control of the muscles in the course of time, especially under the influence of careful training, and in paraplegic rigidity, if the mental acuity be not seriously impaired, laborious treatment may result in an almost normal condition of the limbs by the age of puberty. On the other hand, some cases of generalised rigidity become progressively worse, and succumb, usually before the end of the fourth year. Bilateral athetosis and choreic diplegia, as a rule, follow a very slowly progressive course, without tendency to a fatal result. Paraplegic rigidity apart, a great many of the cases of all forms of diplegia succumb before the sixth year, and in those who survive this age, the tenure of life is short, few reaching far into the third decade of life.

Treatment.—In those cases with a marked degree of mental impairment, and in those which show a course of progressive degeneration, no treatment is of avail. In slighter cases of generalised rigidity, and in paraplegic rigidity, treatment is to be directed to the prevention of the rigidity, to regaining of voluntary control, and the improvement of mental acuity. There is, perhaps, no disease which demands greater patience and persistency in carrying out of suitable treatment, and there are few diseases in which more brilliant results may be produced from apparently hopeless cases by pertinacity in treatment. It is in the early years, when treatment is for the most neglected, that good results are more quickly and readily obtained. From the first, regular massage and passive movements should be employed. Voluntary movement should be encouraged, as far as possible, and as power and movement increase, gymnastic exercises of every kind should be employed. Rigid apparatus for prevention of deformity and to reduce contracture is harmful, for it increases the weight of the limb, and interferes with movement, which is the remedy with which paralysis is to be combated. Tenotomy is of great service in the relief of deformity and contracture, and should be soon followed by passive movements. It should never be performed, unless a fair degree of voluntary power is present. Many of the patients seem to improve more rapidly if thyroid extract be administered in moderate daily doses.

AMAUROTIC FAMILY IDIOCY

I. WARREN TAY-SACHS' DISEASE: THE INFANTILE FORM

Definition.—A family disease of infancy occurring chiefly, but not entirely, in the Hebrew race, affecting children during the first year of life, who are apparently quite healthy when born, and characterised by—(1) progressive mental impairment, ending in absolute idiocy; (2) progressive paralysis of the whole body; (3) progressive diminution in sight, ending in absolute blindness. Pathognomonic retinal changes are constantly present, consisting of a large and conspicuous "cherry-red spot" in the region of the macula, and, in addition, optic atrophy occurs later and (4) a fatal termination in the marasmic state before the age of 2 years.

Ætiology.—Nothing is known of the ætiology of the disease apart from its familial and racial incidence. The tendency to the disease is unquestionably congenitally installed.

Pathology.—This is very striking. It consists of a progressive degeneration of the nerve cells from the highest to the lowest, and ultimately there may be no normal cells remaining anywhere in the nervous system. The degeneration takes the form of swelling of the cell protoplasm, and of the dendrites with chromatolysis, swelling of the hyaloplasm and destruction of the cell fibrils, followed by disappearance of the nucleus, and finally by absorption of the remains of the cell. Every cell of the central nervous system both of the brain, spinal cord and spinal ganglia, is in the end similarly affected.

Symptoms.—There are few diseases in which the *clinical manifestations* are so perfectly uniform as in this malady. The children have all been born at full term, and in perfect health. They thrive well during the first 3 to 6 months of life, when they gradually become listless and apathetic, cease to take interest in the surroundings, and begin to show signs of the visual failure which ends in blindness. Later, the child is unable to sit up, or to hold up its head. The limbs, which may be slightly spastic at first, become flaccid and motionless. There is a gradual increase of all these signs. The mental defect becomes more and more noticeable, the paralysis more extreme, complete blindness follows, and the patient sinks into a condition of marasmus, in which he dies. Convulsions, nystagmus and strabismus are sometimes present.

The retinal changes are pathognomonic and are due to a degeneration and disappearance of the nerve cells of the retina and their processes, which constitute the fibres of the optic nerve. This change is most intense in the region of the fovea centralis, where the retina thins and disappears over a circular area, exposing the vascular choroid. This gives rise to the characteristic appearance, on ophthalmoscopic examination, of a cherry-red spot in the region of the macula. This spot is actually a hole in the retina exposing the choroid. The optic disk shows progressive atrophy.

Diagnosis.—Distinction has to be made between this and other forms of progressive diplegia. The symptoms are so distinct, that a physician, who is acquainted with the disease, and able to recognise the retinal picture, can hardly fail to make the correct diagnosis.

Treatment.—No treatment is of any avail.

2. OTHER FORMS OF AMAUROTIC FAMILY IDIOCY

In addition to the classical *infantile form* described in the preceding article, cases have been observed in which, while the pathological changes are the same as in *Waren Tay-Sachs' disease*, the incidence is non-racial, the onset of the disease is later, the ophthalmoscopic signs are different, and the course is slower. According to the age of onset, these are classified as the *late infantile form* and the *adult form*.² In these two forms, there is no cherry-red spot at the macula. The characteristic ocular change is a disturbance of the retinal pigment—a kind of retinitis pigmentosa—around the macula, with or without optic atrophy; in some cases optic atrophy alone is found; rarely, vision is normal and the fundi are healthy. Otherwise, the symptoms are the same as in the infantile form.

INFANTILE HEMIPLEGIA

While in childhood hemiplegia of slow onset is due to the same causes as in adults, cerebral tumour being the common cause and chorea not an infrequent one, yet the majority of the cases of infantile hemiplegia of rapid onset are examples of diseases peculiar to children, to which no comparable disease occurs in adults, and to such cases the term "infantile hemiplegia" is restricted. These conditions are due to gross organic lesions of the brain, and for this reason must be strictly separated from the cerebral diplegias which are the result of cell lesions and not of gross lesions.

Ætiology.—In two-thirds of all the cases, the onset occurs within the first three years of life. The malady becomes increasingly rare as childhood advances. A few of the cases are of prenatal origin, and some of these have been proved to have been due to injury to the foetal brain from a blow upon the mother's abdomen, while others are due to syphilitic foetal vascular disease. In a third class of mysterious origin, mothers have given birth to several hemiplegic children, examples of which we have recorded. Some of these children are born with definite hemiplegia and contractures. Again, a very few cases are due to obstetrical events during birth, by which the cerebrum is injured. Acute infective diseases play a very important rôle in the causation of the disease, for about one-third of all the cases develop the malady during the course of a known infection. By far the most important of such fevers are measles and scarlet fever, but hemiplegia may occur in the course of pertussis, small-pox, rotheln, diphtheria, dysentery, pneumonia, typhus, typhoid, mumps, malaria, chorea and endocarditis. While there can be no doubt that primary vascular lesions are responsible for a few of the cases in which this condition complicates the specific fevers, whooping-cough, for example, may cause cerebral hæmorrhage; marasmic conditions in any fever may cause thrombosis of cortical veins, and chorea and endocarditis may cause embolism, yet it is certain that in the majority of cases, an inflammatory focal lesion of the brain or encephalitis is the pathological lesion. In cases which arise with no definite ætiological connection, it seems clear that a primary encephalitis is responsible, and in a large number of instances the cerebral form of poliomyelitis is certainly the cause of the malady.

Pathology.—There is but rarely any opportunity for the examination of the brain until long after the occurrence of the primary lesion, and it is sometimes difficult to deduce with accuracy the exact nature of the primary lesion from the end results. The following lesions are met with, either alone or combined in order of frequency: (1) Atrophic sclerosis; (2) cyst formation; (3) shrunk patches resembling wet wash leather, with some degree of atrophic sclerosis in their vicinity, and (4) porencephaly. Of these, the atrophic conditions seem to be the results of encephalitis, which may also cause some cyst formation; the cystic conditions may result from the above, or from hæmorrhage or thrombosis, and porencephaly is certainly due to embolism.

Symptoms.—The onset is rapid, and in two-thirds of all the cases the disease is ushered in by convulsions, which may be unilateral, but are more frequently general, and are frequently repeated during a period of from a

few hours to 24 hours, after which the patient sinks into a subconscious state, from which he gradually emerges in the course of a few days, to show the signs of some cerebral defects, usually hemiplegia, sometimes hemianopia, or aphasia, or any other sign of local cerebral or cerebellar lesion. Pyrexia often accompanies the convulsion, and vomiting is common. In cases due to poliomyelitis, there may be general signs of that disease, in the form of malaise and pyrexia, for some time before the nervous symptoms are manifest. Both with the specific fevers and with poliomyelitis, the onset may be without convulsions or loss of consciousness. We have seen this chiefly in older children, when the cause has been poliomyelitis. The first sign of the cerebral trouble was the weakness of the limbs. The prognosis as regards rapid recovery is much better when convulsions are absent.

The relation of the onset of the paralysis to the convulsion varies. It may reach its height immediately after the initial convulsion, or slight hemiparesis may occur which deepens after each subsequent convulsion. Sometimes the early convulsions leave no paralysis, but this appears towards the end of the first week, either suddenly with fresh convulsion, or gradually, as the patient recovers from the comatose state. The paralysis at its onset is flaccid, and involves the whole of one side of the body to a greater or smaller extent. An initial monoplegia is of extreme rarity. The paralysis may not reach the greatest intensity until the end of the second week. Subsequently it lessens, in some cases disappearing completely in from a few weeks to 3 months; in others, it may show no signs of improvement. The limbs, at first flaccid, subsequently become spastic and develop contractures. In the course of years there may be great arrest of growth on the affected side, and this is not in relation with the degree of paralysis, but apparently depends upon the degree of destruction which has occurred in the parietal lobule. Post-hemiplegic spontaneous movements of an athetoid, choreic or irregular kind are common, and are attributable to lesions in the corpus striatum and subthalamic grey matter, for which regions encephalitis shows an especial predilection. In the early stages of the poliomyelitic cases, the blood shows a polymorphonuclear leucocytosis and the cerebro-spinal fluid shows a marked lymphocytosis, which disappear usually within 10 days. There is increase in the albumin and some decrease in the sugar content. Epileptic fits recur at varying intervals in about half of all cases of infantile hemiplegia. These always commence upon the affected side and are sometimes confined to it. Mental deficiency is met with in all degrees, in relation to the position and extent of the cerebral cortex which is involved in the lesion.

Diagnosis.—The nature of the malady at the onset, with convulsions, may be possibly suggested by prodromal pyrexia, by the severity and long duration of the convulsions, and by the prolonged subconscious state that often follows. At this stage, too, the presence of a marked lymphocytosis in the cerebro-spinal fluid with a polymorphonuclear leucocytosis in the blood strongly suggests poliomyelitis. Convulsions occurring several days after the onset of specific fevers should strongly suggest the diagnosis. When the signs of hemiplegia or of other local cerebral lesions appear, the diagnosis presents no difficulty.

Course and Prognosis.—In a very small proportion of the cases the patient does not survive the initial manifestations of the disease, and dies in

convulsions. Apart from this event, infantile hemiplegia has little tendency to destroy life. The initial flaccid hemiplegia tends to improve and gives place to a slowly improving spastic hemiplegia, which, with the return of some power, shows perversity of movement, stiffness and slowness, ataxy, athetosis and choreic movements or tremors according to the position of the lesion. The spontaneous movements appear within a year of the onset. Slow improvement may go on for years, but cases with much mental reduction or when recurring epilepsy is frequent, improve but little.

Treatment.—We know of no measures that avail to prevent the occurrence or lessen the severity of the cerebral destruction which occurs from encephalitis. Too often the damage to the brain has happened as soon as a diagnosis is possible. When the paralysis has developed, treatment is to be directed to the prevention of rigidity and contractures by regular passive movements, to regaining voluntary control by encouragement and patient exercises, and to the improvement of mental acuity. Where there is much contracture and deformity, tenotomies are of great service, provided there be some voluntary power in the muscles, the tendons of which are to be divided. Recurring convulsions should be treated as idiopathic epilepsy.

SYPHILIS OF THE NERVOUS SYSTEM

Of the known causes of organic disease of the nervous system, syphilis stands first in frequency and importance. Of the many problems presented by syphilis of the nervous system one may be chosen for special reference, namely, the alleged dual nature of nervous syphilis and of the causative organism. It has been maintained that there are two distinct pathological forms of nervous syphilis, namely, primary *parenchymatous* syphilis, as exemplified in tabes and general paralysis, where the initial lesion is held to be in the nerve elements themselves, and primary *meningo-vascular* syphilis, in which the initial lesion is in the blood vessels and meninges. But the dual nature of syphilis implied by these distinctions is subversive of pathological principles, for the initial and fundamental lesion of syphilis, wherever found and at all stages, is a lymphangitis or an arteritis, and very strong evidence would be needed to enforce the conviction that the reaction of nervous tissues to the presence of the spirochæte differs essentially from that of all other tissues of the body. Nor is this view supported by the morbid anatomy of the diseases concerned, for in every case of tabes and general paralysis, vascular and meningeal lesions can be found after death. Moreover, in the vast majority the increased number of cells in the cerebro-spinal fluid shows that the meninges are attacked even in the earliest stages.

For these reasons the trend of opinion is to deny the existence of primary parenchymatous syphilis, and to hold that the vessels and meninges are first injured in all forms of syphilis of the nervous system.

The contention that the virus of syphilis exists in two forms next demands consideration. Of all syphilitics the proportion in whom the nervous system is attacked is small. To explain this low incidence it has been assumed

that neuro-syphilis results from infection by a biological variant of the *Spirochaeta pallida* with special affinities for nervous tissues—the “neuro-tropic virus,” while other forms of syphilis follow infection by the “dermo-tropic virus.” At first sight this attractive conjecture seems to be supported by numerous clinical observations. These are, that in some instances several persons infected from the same source have later developed syphilitic nervous diseases; that the superficial manifestations of syphilis are often mild or absent in those who ultimately develop neuro-syphilis, and that secondary and tertiary syphilis, outside the nervous system of these patients, is rare; also that in Oriental countries where syphilis is common, some forms of neuro-syphilis, namely, tabes and general paralysis, are seldom seen.

But it has never been shown that the persons who formed the source of infection for several cases of nervous syphilis have themselves developed this disease; it can no longer be held that tabetics and paralytics are free from secondary and tertiary lesions—witness the frequency of gummata and of aortitis in these cases; finally, Europeans who contract syphilis in the East are just as likely to suffer from tabes and general paralysis as if they had contracted it at home. It cannot be denied that the secondary phenomena are often so slight as to pass unnoticed by patients who later become tabetics or paralytics, or that patients with severe integumental lesions rarely develop tabes or general paralysis. These facts however, together with a large amount of additional evidence, suggest that the ultimate result of infection depends rather on the individual attacked than on any peculiarity of the infecting agent, and they lend no support to the notion of the duality of the syphilitic virus.

For the purpose of description it is still convenient to describe syphilitic diseases of the nervous system under two headings: Interstitial or meningo-vascular syphilis and parenchymatous syphilis. To avoid misunderstanding it must be emphasised that these are merely clinical aspects of one disease—neuro-syphilis, and that in both forms the primary lesion is in the vessels and meninges.

THE BLOOD AND CEREBRO-SPINAL FLUID IN SYPHILIS OF THE NERVOUS SYSTEM

A normal fluid may be regarded as one with a pressure equal to 150 to 180 mm. of water, a cell count not exceeding 5 per cm., an albumin content of from 0.025 to 0.05 per cent., and negative Wassermann, globulin and Lange's gold tests.

In primary and secondary syphilis, without nervous symptoms, changes are found in the fluid in 80 per cent. of the cases. Increased pressure, lymphocytosis, excess of albumin or a positive Wassermann reaction are found with a frequency which diminishes in this order. The fluid usually becomes normal under treatment, but these changes must be taken as an indication for very thorough treatment in the early stages. If the blood and fluid are both normal at the end of a year, neuro-syphilis is not likely to arise.

In latent syphilis, without nervous symptoms, the blood is positive in about 70 per cent., but changes in the fluid are found in 20 per cent. only. A fluid which is normal in the latent stage almost never becomes pathological later; if it deviates from the normal it is highly probable that neuro-syphilis will develop later.

In early cerebro-spinal syphilis the blood is usually positive, but it is sometimes negative when treatment has been thorough or recent. This indicates that an examination of the fluid is essential when the blood is negative in a case where the diagnosis is doubtful. Cells and albumin are usually greatly increased, the gold test is usually positive, and the Wassermann reaction is positive in almost every case when 1 c.c. of fluid is used in making the test. The blood and fluid often become normal after the first course of treatment, but a relapse occurs frequently and long before the recurrence of symptoms. Vigorous mercurial treatment and 4 or 6 full courses of salvarsan at intervals of 3 months, usually render the blood and fluid persistently negative. If both are normal a year after the fourth course, recurrence is unlikely.

In cerebro-spinal syphilis of longer duration, the reaction in the blood is almost always positive, and the fluid is seldom normal in active cases. A positive reaction in the fluid probably indicates an active process, even in the absence of recent symptoms. A normal fluid indicates a healed process. The inference is that all cases with a positive fluid and a history of cerebro-spinal syphilis should be treated energetically whether fresh symptoms are present or not. The treatment outlined above under early cerebral syphilis usually renders the fluid negative and the indications for prognosis are the same.

In tabes Wassermann's test is positive in the blood in about 70 per cent. of cases; it is often negative in the fluid when the test is done by the original method with 0.2 c.c. of fluid, but with 1 c.c. it is positive in almost 100 per cent. An increase in the number of lymphocytes in the cerebro-spinal fluid as well as an increase in the total albumin with a relative increase of globulin is almost constant. In some cases in which the disease had remained stationary for a long time the cerebro-spinal fluid is normal in every respect.

Lange's colloidal gold test gives useful information when the diagnosis lies between tabes and general paralysis, for the latter gives a typical reaction, but the test is of no value by itself in distinguishing tabes from other diseases of the nervous system.

Treatment by mercury and intravenous injections of salvarsan sometimes renders the fluid normal. It is stated that in such instances relapse is less likely to occur than in other cases, but no exact correlation has been shown to exist between the clinical course of the disease and the presence or absence of changes in the blood and fluid.

Most observers agree that intraspinal therapy has no advantages over intravenous injections—to the patient. The results are equally good with simple drainage of the spinal canal. Further, numerous experiments have shown that considerable quantities of arsenic reach the cerebro-spinal fluid after intravenous injections of salvarsan; indeed, the amount in the fluid may equal that in the blood. For these reasons it appears that the best mode of treatment is by intravenous injections of salvarsan, and spinal drainage, supplemented, of course, by mercury.

General paralysis of the insane.—The Wassermann reaction is strongly positive in the blood and in the fluid practically in 100 per cent. of cases, and an increase of cells and a positive globulin reaction are almost constant. Lange's gold test gives the characteristic paretic curve.

Treatment by mercury and salvarsan may produce slight modification in the reactions, but it has very little effect in checking the progress of the disease.

CEREBRO-SPINAL SYPHILIS

Ætiology.—Cerebro-spinal syphilis (excluding tabes and general paralysis) occurs in about 4 per cent. of all persons who acquire syphilis. The onset of symptoms is commonest from 1 to 5 years after infection, but it may be as early as 2 or 3 months, or as late as 30 or 40 years. The brain is affected more often than the spinal cord, and usually when the main symptoms point to the latter some signs will be found to show that the brain is also attacked.

CEREBRAL SYPHILIS

Pathology.—The disease may begin in the meninges, in the blood vessels or in the bones of the skull. In cases where the main incidence falls upon the *blood vessels*, the arteries at the base of the brain forming the circle of Willis or arising from it, together with their branches, are most often attacked. To the naked eye they show irregularities in size, due to thickening of their walls in circumscribed areas. Proliferation of the intima with a round-celled infiltration of the outer coats—*endarteritis obliterans*—is the characteristic microscopical change. The same changes occur in smaller arteries within the brain or on its surface, and these vessels, as well as those at the base, may be compressed or invaded by disease beginning in the meninges. In each case their lumen is narrowed or obliterated, thrombosis occurs readily, and softening may result in parts cut off from their blood supply. Obliterative changes also occur in the veins and lymphatics, and lead to further impairment of the nutrition of the brain.

The commonest form of *meningeal syphilis* is a diffuse gummatus leptomeningitis at the base of the brain. On the convex surface of the brain it begins most often over the frontal and parietal lobes. The meninges may be affected alone, but more often the vessels are also diseased. In severe cases a gelatinous exudate fills the sub-arachnoid space and extends along the vessels and nerves. Later, the newly-formed tissue organises and forms sclerosed masses of thickened adherent membranes containing numerous small gummata.

Gummata arise in the meninges or spread to them from the skull. They may be numerous, diffuse and small, or large, circumscribed and few in number. Large tumour-like gummata are commonest on the convex surface of the frontal and parietal lobes.

Many important results of cerebral syphilis are due to impaired nutrition of parts not directly affected. Thus softening, hæmorrhage, cyst-formation, atrophy of cells and tract degenerations may occur, and non-syphilitic diseases may be simulated.

Symptoms.—The main incidence of the disease may fall upon vessels or membranes, the lesions may be diffuse or circumscribed, any portion of the brain or any cranial nerve may be affected alone, and every combination of lesions and, therefore, of symptoms, is possible. In many cases their multiplicity, their presence in unusual combinations, and the changes in their intensity and distribution from time to time give a clue to their nature.

Headache is a common prodromal symptom. It is often severe, and is usually worse at night. Sustained mental and physical effort becomes

difficult, the memory is impaired and the character changes. Irritability, intense excitement or delirium may follow, ~~but more often~~ the patient becomes lethargic. At this stage paralysis and localising signs may be absent. In many the pupils are unequal or irregular, or they contract sluggishly to light, and in some the optic disks show blurring of the edges and other signs of early papillœdema.

At any time, with or without prodromata, more definite signs of vascular disease or of paralysis of one or more of the cranial nerves may appear. *Arterial thrombosis* is usually preceded by prodromal symptoms, but it may come on in one apparently well. Its seat of election is the middle cerebral artery or its branches, and weakness of one arm or of one side of the body with or without aphasia is a very common early symptom. The weakness is often slight and transient. If hemiplegia occurs, it takes several hours or a day or two to develop. It is more often a paresis than a paralysis, and consciousness is usually retained. Sometimes the affected limbs are rigid and tremulous. The symptoms of thrombosis in other arteries are given on p. 1451.

In *vertical meningitis*, headache is usually severe, and the skull is often tender over the affected part. It frequently attacks the motor areas, and convulsions are common. They may be confined to one limb or to one side of the body, consciousness being retained, but more often they become generalised and consciousness is lost. In more chronic cases mental symptoms may predominate, the patient becoming slowly demented.

With *basal meningitis* severe deep-seated headache is almost always present. Later a characteristic lethargy with severe impairment of the mental functions may appear. Whilst in this stuporose state the patient can usually be roused, when he answers questions in a sleepy fashion and obeys simple commands, but his memory is bad, and he is unable to give an adequate account of himself. Variations in the degree of the stupor are a striking feature. In some cases profound torpor may persist for several weeks.

Soon after the onset, signs of implication of the cranial nerves appear. Any one of them may be affected alone, but, as a rule, several are attacked, where they lie close together after their exit from the brain, or as they leave the skull through the foramina. Ocular symptoms are rarely absent. Inequality in size, or irregularity in the outline of the pupils, may be the only sign, but diminution of the light reflex, ptosis, squint, diplopia and weakness of the movements of the eyeball are frequent, and papillœdema is common. It is characteristic of the cranial nerve palsies in syphilitic basal meningitis that the symptoms often show great variations in degree and distribution at different times.

The symptoms produced by large *gummata* are those of any cerebral tumour—headache, vomiting and papillœdema; and as the motor region of the cortex is a favourite site for these syphilitic tumours, convulsions are common.

Diagnosis.—Syphilis must be thought of in every case of nervous disease without an obvious cause—indeed no other diagnosis is justified until this has been excluded. The only hope for the patient may depend on its detection and treatment, for it is often curable while the diseases it simulates are not. A history of syphilis or signs of the disease elsewhere are of first importance. Obstinate headache alone should arouse suspicion, and when

signs of vascular or cranial nerve troubles follow a prodromal period of headache and mental impairment, syphilis is the most likely cause.

Jacksonian epilepsy or fits of any kind in patients without an epileptic history are strongly suggestive of syphilitic meningitis or gumma. As a rule, these convulsions are readily distinguished from those of idiopathic epilepsy, by their partial distribution, by the weakness which remains in the parts which were convulsed, and by the presence of papilloedema, of cranial nerve palsies, or of other signs of organic disease which are found in the intervals between the fits. Cerebral new-growths produce similar symptoms, but this diagnosis should not be entertained until syphilis has been excluded. In all cases an examination of the blood and cerebro-spinal fluid is essential (see p. 1484).

Prognosis.—The outlook in cases with mild symptoms is good if the treatment is efficient. In severe cases of syphilitic arteritis it is grave. The vessels most often invaded are large end-arteries, and the softening which results when their lumen is occluded is not amenable to anti-syphilitic remedies. Relapses are common, and patients apparently cured are often seized in a few months with fresh cerebral troubles. The lesions in the meningeal and gummatus forms of the disease are mainly cortical, and large areas of softening are not produced. The prognosis is much better in this form, and complete cure is almost the rule when treatment is begun early. It is often impossible, however, to decide from the clinical signs whether the vessels or the meninges have suffered the more. In the absence of this knowledge the prognosis depends on the results obtained by the use of appropriate remedies.

Treatment.—See pp. 1489, 1493.

SPINAL SYPHILIS

Pathology.—The disease may begin in the bony or membranous coverings of the cord, in the blood vessels on its surface, or in the interstitial tissues within its substance, and spreading from one to the other, usually attacks several of these structures in various combinations. As in cerebral syphilis, many of the changes in the cord are secondary to disease in the vessels or meninges, and appear in parts not directly attacked by specific processes. The commonest form of spinal syphilis is *meningo-myelitis*. The meninges are thickened and adherent, while the spinal and meningeal arteries and veins show obliterative changes, and are surrounded or infiltrated by small round cells. The same changes are apparent in and around the vessels and pial septa within the cord. In severe cases, the membranes are united to form a thick fibrous sheath around the cord, and the outlines of the nervous structures as seen in transverse section are almost obliterated by the presence of numerous small gummata or of myriads of small round cells. The nervous elements are compressed by the cell infiltration, or undergo softening or necrosis as a result of obliteration of the blood vessels. *Meningo-myelitis* is usually confined to a narrow area in the dorsal region, and is often associated with a more extensive meningitis.

In some cases with severe arterial changes, extensive softening results from thrombosis or hæmorrhage and produces severe paralysis of sudden onset—*acute syphilitic myelitis*.

Large gummata are rare. They occur in the cord, or on its surface, and produce the signs of compression.

In another rare form in which the membranes alone are affected—pachymeningitis and leptomeningitis—the dura and pia-arachnoid unite to form a thick fibro-gummatous sheath around the cord to which they become adherent.

Syphilitic disease of the vertebral column is not common. It produces changes which resemble those of tuberculous spinal caries, with osteitis and periostitis, and the formation of granulation tissue and gummata on the outer surface of the dura. Necrosis of the bones may lead to deformity of the spine. It is seen most often in the cervical region, where it begins in the spine, or spreads from a syphilitic ulcer in the throat.

Symptoms.—In meningo-myelitis, pain in the back, tenderness of the spine, and radiating pains or a feeling of constriction in the limb or around the trunk, are often present in the premonitory stage. After these have lasted several days or weeks, cord symptoms appear. They may come on rapidly, or very slowly. Often the first complaint is of numbness or tingling in the lower limbs, or of weakness or stiffness after exertion. Several attacks of temporary weakness may precede severe paralysis, and in different cases every degree is seen, from slight stiffness to complete paraplegia. When the paralysis comes on slowly the lower limbs become spastic, the knee- and ankle-jerks are exaggerated, and the plantar response is "extensor." In severe acute cases the limbs are flaccid and the tendon reflexes are at first diminished or lost, spasticity and increased reflexes developing later. In both forms the abdominal reflexes are diminished or lost below the level of the lesion. In most cases bladder control is impaired, and in some this is the first symptom. Sensory troubles may be slight when the paralysis is severe. Numbness and tingling are common, and some objective loss can usually be detected, the temperature sense, especially for cold, and the sense of vibration being most often at fault.

In one group of cases Erb's syphilitic spinal paralysis spastic weakness develops slowly in the lower limbs, without meningeal symptoms. The bladder is usually affected, and sensory loss is slight. In this form the spinal disease appears later after infection than is usual in meningo-myelitis.

¶ Pachymeningitis and leptomeningitis as an isolated disease is commonest in the cervical region. The earliest symptom is pain in the neck, radiating down the upper limbs and between the shoulders. After a time, usually several months, weakness, wasting and loss of sensation appear in the arms. Still later, spastic paraplegia may develop from compression of the cord. When the lumbar region is attacked, the same symptoms appear in the lower limbs.

In syphilitic caries tenderness over the diseased bones, pain on movement of the spine, and radiating pain in the distribution of the sensory roots at the level of the lesion, are the chief symptoms. When the cord is compressed, power and sensation are diminished in the parts below.

Diagnosis.—Spinal syphilis appears in many clinical forms and often resembles other diseases. Hence it must be considered in every case of spinal disease without an obvious cause. The diagnosis may be founded on—(1) a history of syphilitic infection; (2) the presence of syphilitic lesions in other parts of the body; (3) Wassermann's reaction in the blood or patho-

logical changes in the *cerebro-spinal fluid* (see p. 1484); (4) signs of associated cerebral syphilis; (5) rapid improvement under treatment by specific remedies.

Prognosis.—The outlook for recovery of power is good when the meninges only are attacked, but bad when the symptoms are due to softening, hæmorrhage, atrophy of motor cells, or tract degenerations, for these are secondary changes and are not influenced by anti-syphilitic remedies. In a given case, however, it is not possible to assess accurately the amount of damage sustained by different structures, and the prognosis is always doubtful. Complete recovery occurs in about one-third of the cases of slight or moderately severe meningo-myelitis. The majority make a partial recovery, and are able to walk fairly well, in spite of the weakness and stiffness which remain. In cases with a sudden onset of severe paralysis, the prognosis is very bad, and death from bedsores or bladder and kidney infection is the usual result. On the other hand, the outlook for recovery of power is better when slight troubles come on rapidly than when they develop extremely slowly, as in Erb's form of the disease, in which many years pass before the paralysis becomes severe; for in the first case the lesions are interstitial and they respond well to treatment, whereas parenchymatous degeneration of the nervous elements themselves is present in the latter, and treatment is of less avail. The prognosis in early cases is determined by the effects of anti-syphilitic treatment. In cases of long standing, the most that can be expected is that appropriate treatment will arrest the course of the disease.

Treatment of Cerebro-spinal Syphilis.—As soon as the diagnosis is made, vigorous anti-syphilitic treatment should begin. The drugs used are mercury, potassium iodide, and the arsenical preparations, salvarsan and its derivatives. Of these mercury still stands first. Its use should never be omitted. However given it should be pushed until the gums become sore, or salivation is produced. When the treatment can be supervised, one of the best methods of giving mercury is by inunction. A drachm of the blue mercurial ointment, or of the oleate of mercury, should be rubbed into the skin daily for a week, and then on alternate days, until sixty inunctions have been made. By choosing hairless parts and by changing the site from day to day the requisite amount of mercury can be given in this way without trouble. Another method of giving it is by intramuscular injection. A grain of metallic mercury in the form of a cream is injected into the buttock at weekly intervals until seven doses have been given. This method, though useful when large numbers have to be treated, has many disadvantages and is not suitable for ordinary practice.

Subcutaneous injections of an aqueous solution of the biniodide of mercury are very efficacious. This method is much used in France. A solution containing 2 or 3 centigrammes of biniodide per cubic centimetre is prepared, and 3 or 4 centigrammes are injected daily in one or two doses. Twelve or fifteen consecutive injections are given. They are then stopped for a fortnight. Several successive series of injections may be given, if it is deemed necessary.

After a preliminary course of inunctions or injections, the treatment is continued most conveniently by the use of pills containing 1 gr. of grey powder and $\frac{1}{4}$ gr. of opium. For several months these pills should be taken daily up to the limits of the patient's tolerance. If the gums become sore, or if the digestion is impaired, the number can be diminished and then

again increased. Tolerance increases rapidly with continued use. The pills should be taken for at least 2 years after the onset of nervous troubles, and for several months in every year, during the rest of the patient's life. The teeth should be kept clean, and an alum mouth-wash should be used daily.

In view of the undoubted spirochæticidal powers of salvarsan and allied preparations in early syphilis, it is advisable also to give them in nervous syphilis. This, however, must not be allowed to interfere with the one essential part of the treatment, namely, the thorough and prolonged administration of mercury. The usual course consists of a series of 7 weekly injections of 0.6 gramme of neo-salvarsan. This may be repeated at 6-monthly intervals, if necessary. Potassium iodide is a useful adjuvant to mercury, but it is not an essential part of the treatment.

Massage and passive movements should be carried out daily, when the limbs are weak. When sensory loss is present, careful nursing is necessary to prevent the formation of bedsores; and when control of the bladder is defective, the usual precautions must be taken for the prevention of infection of the urinary tract.

GENERAL PARALYSIS OF THE INSANE

Ætiology.—As in tabes, the essential factor in the causation of general paralysis is previous syphilitic infection. Males are affected much more frequently than females. The onset is commonest between the ages of 30 and 50 years, from 10 to 20 years after infection. As a result of congenital syphilis or of early innocent infection, it may appear in childhood, youth or even adult life. It has been estimated that about 5 per cent. of syphilitics develop general paralysis, but the incidence in those who have been well treated in the early stages is not more than 1 per cent. The incidence varies in different races, and seems to be greater with increasing civilisation. It is more apt to occur in town and city dwellers, and in those who have led a strenuous intellectual or business life.

Pathology.—The skull-cap is thickened, especially in its anterior part, its density is increased, and the diploë is obliterated. The dura mater is thickened and adherent to the skull, and may show the changes of pachymeningitis hæmorrhagica. The arachnoid is tough and thick, and white lines are seen between the sulci and along the vessels. The pia is thickened, its meshes are distended by pale yellow fluid, and on attempting to strip it off portions of the cortex are torn away. The amount of cerebro-spinal fluid is increased. The brain looks wasted and shrunken, and its weight is abnormally low. The sulci are wide and the convolutions are narrow. The ventricles are dilated, and their ependymal lining presents a granular or a frosted appearance. On section the grey matter of the cortex is seen to be thinner than normal—decortication. On histological examination gross changes are found in the membranes, in the blood vessels, in the neuroglia, and in the true nervous elements. The earliest changes are found in the cortical vessels and membranes. Nuclear proliferation occurs in the walls of the smallest pial vessels and in the perivascular lymphatics. There is overgrowth of the endothelial cells in the capillary walls, and around them lie peculiar cells—the so-called plasma cells. Small lymphocyte-like cells,

most cells, and many others of doubtful nature appear in and around the perivascular channels, and by blocking them interfere with the nutrition of the cortex. The larger vessels also show proliferation of the endothelium, degeneration of the muscular coat and perivascular infiltration. The spirochaetes are readily demonstrated in the brain substance.

The fibres of the neuroglia proliferate, its cells multiply, and some assume an abnormal size or shape. These changes in the interstitial tissues are followed by degeneration of the cortical cells and atrophy of their processes. The changes are most marked in the cortical cells and association fibres of the anterior part of the cerebrum, but similar degenerations are found in the basal ganglia, the cerebellum, the brain stem and the spinal cord.

Symptoms.—The disease is characterised by progressive deterioration of the mental and physical powers.

MENTAL SYMPTOMS.—The most recent acquisitions are usually lost first. Hence the earliest sign of mental failure will differ according to the intellectual and emotional make-up of the individual attacked. Memory, judgment and reasoning are impaired from the first, the aesthetic, moral and intellectual attributes alter early, and changes occur in the domains of conduct and emotion which astonish or distress the patient's friends. To one who sees the patient for the first time the defects may not be apparent, but those who know him will speak of the *changes* in his intellectual capacity, character or behaviour. Cheerfulness has given place to depression or irritability, the quiet and unassuming man has become passionate and boastful, the good father has turned against his family, promises are no longer kept, a good business is neglected, money is spent unwisely, high artistic skill is lost, the moral code is transgressed, and so on. There is no end to the variety of the early symptoms, but in each case they represent a change for the worse.

In the classical form of the disease, elation and expansive delusions concerning health, wealth, social position or physical and athletic powers are prominent, but in a larger number of cases the patients are depressed in the early stages, and the delusions when they appear may be melancholic or hypochondriacal. Unlike the paranoiac, who may refuse to disclose his delusions or who may reason skilfully from his false premises, the parietic reveals his delusions readily, and can be made to betray their falseness by his own words. To the direct question regarding his occupation the Emperor, the possessor of untold wealth, the world's greatest general, will reply unconcernedly that he is a boot-black, or the champion athlete of the universe will give answers showing a complete absence of familiarity with any branch of sport.

In the course of time dementia increases, memory is abolished, delusions are forgotten, emotion disappears, and in a year or two the patient is unable to move from his bed where he lies speechless, paralysed, and incontinent. The various concomitants of the delusions are described in the following paragraphs.

The most constant and most characteristic signs are changes in the pupils, tremors of the face, tongue and hands, and disorders of speech. Changes in the pupils occur early, indeed they are often present as signs of past syphilis before symptoms of general paralysis appear. Inequality in

size, irregularity in outline, and the complete or incomplete Argyll Robertson phenomenon, are very common pupillary signs. Primary optic atrophy is frequent, but except in tabetic cases it is rarely complete. Paralysis of the external ocular muscles and papilloedema sometimes occur as a result of associated tabes or cerebral syphilis. Tremor is often an early sign. In the face and hands, though often present when the parts are at rest, it is best seen in speaking or when movements, such as showing the teeth and holding the arms outstretched, are carried out to order. The typical tongue tremor is a backward and forward "trombone" movement of the organ, when the attempt is made to protrude it. Speech is often affected early. The defects comprise disorders of articulation and of memory and ideation. At first it is merely hesitant. Later the lingual and dental consonants become blurred, syllables are omitted, interpolated or slurred, and the voice becomes feeble and lacks intonation. As the memory fails, confusion arises in the construction of long sentences, proper names are forgotten, the choice of adjectives and verbs becomes more and more limited, and the vocabulary diminishes until only interjections are left. Written language suffers in the same way, and may show defects of execution and of ideation before spoken speech is noticeably altered. At the onset voluntary power in the muscles is usually maintained, but undue fatigue after moderate exertion is a common early symptom. As the disease progresses, weakness appears in the lower limbs and soon affects all the muscles. Some of the signs of injury to the pyramidal tracts, such as increased tendon reflexes, diminution or loss of the skin reflexes, and Babinski's plantar response, are found sooner or later in almost every case. In a small number the tendon reflexes are abolished and other signs of tabes, such as sensory disturbances, are present. Retention of urine or incontinence sometimes occurs in the early stages. Towards the end, control of the bladder and rectum is always lost.

Epileptiform seizures of various kinds are common. They may be the first obtrusive symptom, and may occur at any time in the course of the disease. The attacks may have all the aspects of idiopathic epilepsy, or they may be local and of the nature of Jacksonian fits. Attacks resembling *petit mal* have also been observed. In the so-called "congestive" apoplectiform attacks, paralysis of one limb or of one side of the body comes on suddenly with or without convulsions and passes off in a few days or weeks. The patient may become comatose and breathe stertorously, or he may be merely somnolent or confused.

Insomnia is frequent in the prodromal period, but in the early stages sleep is often excessive. Later, sleeplessness and motor restlessness are often troublesome symptoms.

CLINICAL TYPES.—*Exalted or expansive form.*—This form includes the cases in which elation, euphoria and grandiose ideas are prominent.

Demented forms.—The patients often seek advice of their own accord, complaining of diminished mental and physical power, or failing memory. Mental deterioration runs its course without marked depression or exaltation.

Depressed form.—This common form is characterised by melancholic and hypochondriacal delusions. Some have delusions of persecution. Very often the patient exaggerates his afflictions to a degree not seen in other forms of insanity, melancholic megalomania. Remissions are common.

Maniacal form.—The features of this form are attacks of acute maniacal excitement, which may resemble acute delirious mania. Remissions are common, and apparent complete recovery may be made; but the attacks recur, each one leaving the patient more demented.

Many other varieties have been described, the stuporose, the convulsive, the tabo-paretic, and so on. The characters of these types are sufficiently indicated by the names.

Course and Prognosis.—After an insidious onset, the disease progresses steadily and usually ends fatally in about three years. Acute forms may run their course in a few weeks. When convulsions are frequent, death usually results in about six months. When periods of extreme restlessness and excitement alternate with depression, one year is the average duration. In simple demented and depressed forms, the duration is usually about 3 years. The course is most prolonged in those who have attacks of wild excitement or mania, as remissions are very common in this form. During the remissions, patients may be able to return to work, and 10 years may elapse between the first attack and the fatal termination. The course is often prolonged in women, in congenital cases, and in cases of tabo-paresis.

Treatment.—As some cases of cerebral syphilis simulate general paralysis, in every instance where the latter disease is suspected rigorous anti-syphilitic treatment should be tried in the hope that the patient is suffering from the more curable condition. Admission to an asylum should not be delayed when mental changes render the patient a danger to himself or to his fellows.

Malaria therapy in general paralysis.—Encouraging results have been obtained by infecting paralytics with benign tertian malaria. Blood is obtained from a patient suffering from malaria (not necessarily during a rigor), and is injected subcutaneously or intravenously. The incubation period may be as long as a fortnight or more after subcutaneous injection, but failure to infect with 5 c.c. of blood is rare. If the blood has to be transported it should be received in a sterile test-tube containing glass beads; after defibrination it is transferred to another sterile tube and packed in ice, when it will remain active for 6 hours or more. The recipient is allowed to have six, ten, or more rigors, the number depending on his general condition during the treatment; the infection can be cut short at any moment with quinine; relapses never occur in this experimental malaria. In favourable cases a remission occurs, improvement continuing for several months; the end result of the treatment cannot be assessed until 6 months or more have elapsed. Several of Von Wagner-Jauregg's patients treated in 1917 are still perfectly well. This pioneer obtained 44 per cent. of complete remissions in a series of 141 cases. Gerstinann's figures are 45 per cent. complete remissions, 30 per cent. improved. Yorke and Macfie treated 80 asylum (i.e. advanced) cases and report 27 per cent. fit for discharge. These and many other equally favourable results are to be compared with the incidence of spontaneous remissions in this disease, namely, 11 per cent.; they indicate clearly that malaria therapy should be tried in every case at the earliest possible moment.

TABES DORSALIS

Synonym.—Locomotor Ataxia.

Ætiology.—Tabes is a common and important disease of the spinal cord. It is more frequent in men than in women (10 to 1), and begins most often between the ages of 30 and 45. The essential factor in its causation is previous syphilitic infection. The interval between infection and the onset of symptoms varies from 2 to 20 years; commonly from 5 to 10 years. As a result of congenital syphilis, or of infection in infancy, it sometimes begins in childhood, youth, or early adult life—infantile or juvenile tabes. Occasionally husband and wife are both affected—conjugal tabes.

Pathology.—The essential and primary spinal lesion in tabes is degeneration of the afferent neurones in the posterior (sensory) roots. Some of the degenerated fibres end around cells in the grey matter soon after they enter the cord, while all the fibres with a long intraspinal course enter the posterior columns, and ascend in them to the nuclei of Goll and Burdach in the medulla. As a secondary change the neuroglia around the degenerated fibres increases in amount and density. Hence the characteristic feature in sections of the cord in tabes is sclerosis of the posterior columns. The sclerosis usually appears earliest in the postero-lateral columns of the lower lumbar and upper sacral regions. In the dorsal and cervical cord it is confined at first to the postero-internal columns, which contain the degenerated fibres from the lumbar and sacral regions, but in advanced cases when the dorsal and cervical sensory roots are also affected the posterior columns are sclerosed throughout.

In advanced cases the endogenous tracts of the posterior columns show degeneration, and in some the afferent tracts in the lateral columns are also affected. In sections stained by the Weigert-Pal method the diseased areas are paler than the rest of the white matter. By the Marchi method parts containing recently degenerated fibres show numerous black dots, which represent fatty material in the degenerating myelin sheaths.

In cases of long standing, atrophy of the entire sensory root with degeneration in the peripheral parts of the sensory nerves, and atrophy of cells in the ganglia are frequent findings.

Optic atrophy and degeneration of the spinal roots of the trigeminal nerves are the most frequent cerebral lesions. Of the motor nerves, those supplying the muscles of the eyeball are most often affected. The degeneration is usually peripheral, the nuclei showing no changes. Occasionally the cells in the nuclei of the vagus and hypoglossal nerves are degenerated.

The frequency of excessive sweating on the face, and of ptosis and spinal myosis in tabes, indicates that sympathetic fibres are attacked in this disease. Degeneration of the intermedio-lateral tract in the upper part of the cord and in the medulla has been found in many cases. The sympathetic ganglia and nerves are almost always normal.

Certain as it is that tabes never occurs apart from syphilis the exact relation between them is still debated. For long the view prevailed that syphilis merely rendered the neurones vulnerable to influences which would not damage healthy tissues, that syphilis alone could not cause tabes, and that some other factor acts as an exciting cause. The term para-syphilis

was used to express this indirect relation between syphilis and certain of its nervous manifestations, particularly tabes and general paralysis. The discovery of spirochætes in the brain and cord of patients dying of these diseases, however, caused this view to be abandoned, and it is now agreed that all forms of nervous syphilis are a direct result of changes produced by the spirochæte or its toxins.

The researches of Richter have proved that the primary essential and constant lesion in tabes is a syphilitic inflammation which begins at that point proximal to the ganglion where the anterior and posterior roots approach one another and form the radicular nerve of Nageotte. Beginning in the lymph spaces of the sheath which is formed by the fusion of the dura and arachnoid, the inflammation spreads inwards along the septa between the nerve bundles, and as sclerosis occurs the nerve fibres themselves are slowly destroyed. The degenerations in the posterior columns are secondary to the lesions so produced. The anterior roots usually escape because they pierce the common sheath and leave the sub-arachnoid space before they reach the point at which the inflammation begins.

The reaction of the tissues to the spirochæte at the site of this tabetic lesion is mainly a *fibroblastic* inflammation which differs in nature from that which is seen in the pia mater, where a perivascular and diffuse *lymphocytic* infiltration occurs. Richter has demonstrated the spirochæte in the lesions.

Inflammation of the pia mater is a common accompaniment of tabes, but plays no part in its production.

The affection of the cranial nerves in tabes is a result of an interstitial inflammation which attacks the nerves in the proximal part of their extra-cerebral course. In all except the olfactory and optic nerves the inflammation has the same characters as that seen in the nerve roots. These two nerves differ entirely from the spinal roots and the remaining cranial nerves in that they possess a sheath derived from the pia mater and their supporting tissue is glial and of ectodermal origin, whereas the sheath and supporting tissue of the latter are derived from the arachnoid and are purely mesoblastic. The inflammation in these two nerves begins in the pial sheath, and the nerve fibres are damaged secondarily by the same mechanism which destroys the spinal roots; but in this case, owing to the different nature of the tissues affected, the histological characters of the lesions are different. They are, in short, the same as those produced by the action of the spirochæte on the pia and glia elsewhere, and vascular lesions and perivascular infiltrations are prominent.

Symptoms.—The inadequacy of current descriptions of the clinical manifestations of tabes is shown by failure on the part of those who depend upon them for guidance to diagnose the disease before it has reached an advanced stage. So long as tabes is described as a disease characterised by severe lightning pains, absent knee-jerks and Argyll Robertson pupils; so long as the diagnosis is withheld until these symptoms are found together; so long as patients without ataxy are stated to be in the *early* or preataxic state—just so long will valuable years be wasted, as they are at present, before patients receive treatment at a time when it may reasonably be expected to arrest the course of the disease. It is true that these important symptoms appear ultimately in a very large proportion of the cases, and they are often present when the patient is seen for the first time. It is equally

true, however, that many of these patients have complained of symptoms which, if they had been appreciated by the physician, would have betrayed the disease many years before, and that throughout these years they have presented physical signs which, although the knee-jerks and pupillary reactions were still present, would have made the diagnosis of tabes certain. In the following paragraphs stress will be laid on the signs that appear early and allow the diagnosis to be made at the onset of the disease. Chief amongst these early symptoms are disturbances pointing to interference with the functions of the posterior nerve roots.

SENSORY DISTURBANCES.—*Subjective.*—Following a general law the first manifestations of altered function are subjective—the patient complains of sensory troubles before any changes can be discovered by objective examination. The most important of these subjective troubles in tabes are the so-called lightning pains. These pains merit the closest attention. They are rarely absent, they often precede other symptoms by 5 or 10 or more years, and most important of all they possess peculiar features which render them pathognomonic of tabes and allow the diagnosis to be made in a syphilitic on their presence alone. Although they are rarely absent careful interrogation may be needed to disclose them. To the question, “Have you had any pains?” the patient may answer “No.” He may even be led into denying stoutly that he has even suffered in any way at any time. If then he is asked if he has rheumatism, he will often answer “Yes,” and proceed to give an account of characteristic tabetic pains of several years’ duration. In other cases the patient mentions his pains, but their significance escapes notice because it is thought that they are too slight for tabetic pains. It must be made clear at once therefore that the peculiarity of the pains in tabes does not lie in their severity, for they vary from a trifling sensation of discomfort to almost intolerable agony, but in their distribution, in their direction of propagation and especially in their arrangement in time.

As a rule, they come on in **attacks**, in which single momentary pains are repeated at intervals of a few seconds or minutes for several hours, the whole bout lasting several days or weeks. Between the attacks there may be long intervals of complete freedom from pain. The pains are felt most often in the lower limbs, but any part may be affected. They may be referred to the skin, to the muscles or to the bones. They are very common in the bony prominences around the knee and on the foot. The direction of radiation varies. In some the pain seems to shoot up or down a limb, but in a larger number it seems to strike the limb vertically as if a sharp object were piercing it from without. Some patients experience both kinds of pains. The onset of each pain is always sudden. If it is severe the patient may cry out, and if it overtakes him whilst walking he is forced to stop and he may fall. The duration of each pain is usually momentary, but sometimes it lasts a second or two and fades away gradually. During a given bout the pains usually recur in the same place each time for several hours on end, and then appear in another part, say on the following day. In a few cases, however, they confine themselves to two or three points, now appearing in one and now in the other. In a still smaller number the site varies from moment to moment, so that the patient never knows where the next one will strike him. In one group the pains are repeated very rapidly in one

place for a few seconds, and then after an interval in another, so that the timing recalls the sound of a machine-gun firing short bursts—tap, tap, tap, pause, tap, tap, tap, pause, and so on with a longer interval now and then during which the gun is trained on a new objective.

Compared with the preceding characters the kind and intensity of the sensation experienced is of minor importance for diagnosis. It may be "a niggling under the skin," "like the prick of a pin," "like a hat-pin going in," "like a shock of electricity," "like being suddenly crushed in a vice," and so on. Almost every patient uses a different expression. Let it be repeated, therefore, that it is not the severity or nature of the pains that makes them peculiar to the disease, but their arrangement, place and direction.

After a bout the skin is often tender, and ecchymoses may appear over parts in which the pains were felt. Cold, changes in the weather, anxiety and especially over-exertion make the pains worse. They are often more severe for a day or two after treatment by intravenous or intrathecal injection of specific remedies. Other pains with characters which are not peculiar to tabes are common. They are described as aching, burning or gnawing pains. Like the lightning pains, they alter with changes in the weather and are usually attributed to rheumatism. Other common subjective sensory symptoms are "pins and needles" in the extremities, a feeling of walking on a soft substance, and of constriction around the trunk or limbs. More important than these, because it often appears very early, is hyperæsthesia of the trunk, especially in its lower part. Light touches or applications of water at certain temperatures are almost unbearable. This is well seen when patients are being placed in position for a lumbar puncture. On feeling gently for the bony landmarks, the patient squirms on the table, and the application of iodine causes such vigorous movements that the success of the operation seems to be in doubt. And yet the passage of the needle causes little or no pain, because the pain sensation is already much diminished when hyperæsthesia to other forms is well marked. This hyperæsthesia on the trunk is often associated with a degree of activity in the abdominal reflexes that is rarely seen in other diseases.

Objective sensory disturbances.—Signs of damage to the posterior nerve roots appear in the earliest stages of the disease, and are demonstrable in many cases long before the classical signs appear. The detection of this early sensory loss is of great importance, for its distribution is pathognomonic. The parts in which sensation is first impaired are—(1) a band on the chest and along the inner border of the arms; (2) the feet; (3) around the anus; (4) on the nose.

As the disease advances sensory loss extends upwards from the feet, downwards from the chest, and outwards from the nose and anus in concentric circles. Ultimately these areas coalesce, and in the later stages sensation is diminished all over the body. All forms of skin sensation are not equally affected. Sometimes the defect is first discovered on testing with light tactile stimuli, but more often pain and temperature are first impaired.

The senses of deep pain and of position and passive movement, as well as the vibration sense, are often diminished in the legs in the early stages. In advanced cases these defects are present in all the limbs.

In cervical tabes sensory disturbances occur first, and are most severe in the arms.

In severe cases sensation of all kinds may be almost completely abolished. No cutaneous stimuli are felt and the deep structures are insensitive to pain. To this is added loss of the sense of position, not only in the limbs but also in the trunk, so that the patient is unaware of their position when his eyes are closed. If he sits up with the arms outstretched, on closing his eyes the arms "wander," the fingers execute slow "piano-playing" movements, and the body sways. In extreme cases the patient falls on his side as soon as the eyes are closed.

MUSCULAR HYPOTONIA AND THE TENDON REFLEXES.—Loss of muscle tone occurs in lesions of various parts of the nervous system, and is not necessarily accompanied by changes in the reflexes in the limbs, but when it results from interruption of the spinal reflex arc the two signs are found together. Hence in tabes, where the afferent limb of the reflex arc is the first structure affected, hypotonia and diminution of the tendon reflexes are characteristic signs. The decrease in the tone of the muscles is often well marked when lightning pains are the only symptom of tabes, and loss of skin sensation the only other sign. It is shown by flaccidity of the muscles, and by an abnormal range of active and passive movement of the limbs.

The leg can often be raised to an angle of 100° from the horizontal, with the knee extended, whereas a normal person cannot raise it more than 60° , and excessive range of dorsiflexion of the foot is often a striking sign. In extreme cases the legs can be made to encircle the neck, the body can be flexed so that the head touches the bed between the knees, and the patient is able to imitate the tricks of the "double-jointed" man.

The knee-jerks are very often absent when the patient is first examined, and in the later stages they are almost always lost, but compared with the signs already mentioned this one is of late onset, and may be missing even in the ataxic stage. The position formerly held by the knee-jerks in the symptomatology of tabes should be given to the tendo achillis (ankle) jerks. Loss of the ankle-jerks is indeed an early sign in tabes, for it often precedes loss of the knee-jerks by many years. The tendon reflexes persist longest when optic atrophy appears early. Even in these cases it is unusual to find both ankle-jerks still present, whereas brisk knee-jerks are common. The tendon reflexes in the upper limbs are lost early in cervical tabes, and are frequently absent in cases of the ordinary type.

The skin reflexes are often exaggerated to a degree rarely met with in other diseases. This is best seen on the abdomen, and is usually associated with hyperæsthesia to touch and temperature. Later, when the tactile sense is lost, the skin reflexes are often diminished. The plantar reflex is usually normal. It is sometimes absent when sensory loss on the soles is severe, and in cases where sclerosis of the pyramidal tracts exists as a complication of tabes the response is "extensor."

ATAXIA.—The fibres conveying those afferent impressions which are essential for the equilibration of the body, and for the proper execution of voluntary movements, are more resistant than those with other functions, and inco-ordination, though extremely characteristic of tabes, is usually a late symptom, or it may be absent throughout the whole course of the disease. Its onset is marked by unsteadiness in walking and difficulty in maintaining the balance of the body. These troubles are first noticed when co-ordinated movements are performed without the aid of vision. As the defect increases

unsteadiness appears even with visual guidance. To maintain their balance the patients walk on a wide base with the eyes directed to the ground. At a later stage some raise the feet too high, throw them too far forward and bring them down forcibly, the whole sole striking the ground at once—stamping gait. Others reel from side to side like drunken men. Still later the support of one or two walking-sticks is required, and ultimately walking becomes impossible. The inco-ordination is not only present in walking, but can be seen in all voluntary movements, *e.g.* in the heel to knee test. The same defects occur in the upper limbs. At first there is merely clumsiness in performing fine movements such as picking up small objects and in adjusting the dress. In the end the ataxia may become so great that the patient is unable to feed himself.

By appropriate tests inco-ordination can usually be disclosed before the patient has noticed it. Some of the tests are: standing with the heels and toes together, standing on one foot, walking backwards, rising quickly from a stooping position and turning quickly in walking. In each instance the unsteadiness is greatest when the eyes are closed and when the feet are bare.

SPHINCTER TROUBLES.—Disturbance of the bladder functions is often the patient's first serious symptom. Difficulty in beginning micturition and incontinence, especially at night, are common complaints. Complete retention and paralytic incontinence are rare. In many cases emptying of the bladder is incomplete, and though this causes little discomfort it is serious, as it often leads to cystitis and ascending infection of the urinary tract, which causes the death of many tabetics.

OCULAR SYMPTOMS.—Changes in the reaction of the pupils and in their size and form are very frequent and are of great importance for diagnosis. The chief of these is the Argyll Robertson phenomenon, in which the pupil contracts on accommodation but not when exposed to light. This sign appears in both eyes in 70 per cent. of cases, and is one of the earliest to appear. It is sometimes found in one eye with a normal or diminished reflex in the other. It may be present in an incomplete form, the contraction to light being slight and sluggish when the reaction to accommodation is brisk, or the pupils may contract when first exposed to the light only to dilate again. Occasionally the pupils are fixed and do not react to either stimulus. In rare cases the reaction to accommodation is lost while the light reflex persists.

The size of the pupils varies greatly in different cases. Most often they are small, but pupils of moderate size are very common, and sometimes they are widely dilated. It is not unusual to see pupils which, when contracted on accommodation, are no larger than the head of a pin, but the "pin-point" pupils are extremely rare. Inequality of the pupils or irregularity in their outline is present in most cases. It is said that the pupils are sometimes normal in every respect even in the advanced stages of the disease.

External ocular muscles.—In the early stages transient palsies of the muscles of the eyeball often cause ptosis, diplopia or squint, lasting a few days. Permanent paralysis may come on at any time, but is most frequent in the later stages. A persistent drooping of the eyelids—tabetic ptosis—is a common sign. This is attributable to a lesion of sympathetic fibres. The patient tries to overcome the defect by contracting the frontalis muscles, and the wrinkling of the forehead with slight drooping of the lids

gives the patient an expression—the tabetic facies—by which the disease may be recognised at a glance.

Optic atrophy.—Defective vision from atrophy of the optic nerve is often the symptom for which the patient first seeks relief. It occurs in about one case in ten, and almost without exception ends in complete blindness. The loss usually begins in the periphery of the visual field, and is often unnoticed until central vision begins to fail. Occasionally central vision fails early. At first one eye suffers more than the other, but ultimately, after a period which averages 5 years, all vision is lost in both. Patients sometimes relate that their blindness came on suddenly, or in a few hours or days. In these cases optic atrophy has been present for a long time, but the fibres subserving central vision have escaped until the last. On the other hand, vision may fail very slowly, with periods of arrest or apparent improvement, and total blindness is sometimes delayed for 10 or 15 years. The atrophy is primary, that is, it is not preceded by papilloedema. Pallor appears first on the temporal side, whence it spreads over the whole disk. The edges of the disk are sharply defined and the lamina cribrosa is visible as slightly darker spots, so that the disk stands out clear and bright, like a full moon. When optic atrophy is the first symptom, it is often impossible to detect any inco-ordination in the lower limbs, and ataxia may be long delayed. The knee-jerks are often brisk, but some of the early signs—lightning pains, sensory disturbances or loss of one or both ankle-jerks—are almost always present, and the Argyll Robertson pupil is a constant accompanying sign. In a number of the patients with optic atrophy the signs of general paralysis are added to those of tabes (tabo-paresis), and the course of their illness is that of the more serious disease.

OTHER CRANIAL NERVES.—The senses of smell and taste are sometimes lost. Vertigo, tinnitus and nerve deafness are common. Lightning pains are often severe in the distribution of the trigeminal nerve, and loss of sensation on the nose, especially to pain, is one of the earliest and most frequent signs. Paralysis of the vocal cords, though rarely sought for, is present in many cases.

VISCERAL CRISES.—Various peculiar disturbances of the viscera occur in tabes. They come on in paroxysms, often with great pain.

Gastric crises.—The organ most subject to crises is the stomach. Attacks of severe abdominal pain with repeated vomiting come on suddenly. They last a few days, or a week or two, and are often repeated every few weeks for long periods. Sometimes pain or vomiting alone is present. The patient looks very ill during the attack, but it is never fatal. They often occur before other symptoms of tabes appear, and are often mistaken for acute obstruction, and other conditions requiring urgent surgical treatment, but careful examination will rarely fail to reveal indubitable signs of tabes. If attention were paid to the ankle-jerks, and to sensory disturbances, instead of to the knee-jerks, unnecessary operations would be less frequent.

Next to the stomach, crises are most frequent in the larynx (laryngeal crises). In the commonest form there is spasm of the larynx, with noisy breathing, cough and dyspnoea. Sometimes the attacks resemble whooping-cough or laryngismus stridulus. They are much shorter than gastric crises, rarely lasting more than an hour. Death in an attack is extremely rare.

Attacks of tenesmus (rectal crises) are not uncommon. Attacks of

frequent painful micturition (vesical crises) and of pain like renal colic (renal crises) are rare.

Cardiac, nasal, bronchial, intestinal and other crises have been described.

VASOMOTOR AND TROPHIC DISTURBANCES.—The most important of these are changes in the joints and perforating ulcers. ~~Rarer forms are local sweating, loss of hair, nails or teeth, attacks of herpes, hæmorrhages into the skin, necrosis, rarefaction and spontaneous fracture of bones, excessive callus formation and spontaneous rupture of tendons.~~

Charcot's joint disease.—Arthropathies may develop at any stage of the disease. Occasionally the patient seeks advice for the first time with this complaint. The first sign is usually rapid swelling in and around a joint, with effusion and œdema. The effusion, in slight cases, subsides slowly and the joint recovers, but more often the enlargement is followed by destruction of the cartilages, wasting of the ends of the bones, peri-articular new-bone formation and destruction of the ligaments. The joint becomes disorganised, the range of movement is increased, and crepitations of startling coarseness are heard and felt when the part is handled. The characteristic feature is the complete absence of pain. Dislocations occur readily, especially at the hip. The diseased joint sometimes becomes infected. This is commonest in the foot. The joints most often attacked are, in order of frequency: knee, hip, shoulder, elbow, ankle, small joints of the hands and feet, the spine.

Perforating ulcers are commonest on the sole of the foot. Patches of hard thickened skin are frequently seen on the soles of the feet. Sometimes blisters form beneath this thick epidermis, and on bursting leave an indolent sore. Once formed the ulcer is very indolent. It is usually painless.

Complications.—Tabes is frequently complicated by other syphilitic affections of the nervous system, of which the commonest and most important is general paralysis of the insane. Many tabetics develop general paralysis, and most paretics present some of the signs of tabes. Indeed, these conditions are merely different aspects of the same disease, and are named according to the predominant features. Sometimes it is difficult to decide the category of given cases, and the name tabo-paresis is used to describe them. Occasionally the pyramidal tracts degenerate and signs of spastic paraplegia are added to those of tabes. Atrophy of the anterior nerve roots and wasting of the corresponding muscles is a fairly common complication. Outside the nervous system the commonest complications are arthritis, aortic regurgitation and aneurysm.

Diagnosis.—Most tabetics come under observation for the first time when one of the many symptoms of the disease begins to cause serious trouble. The obtrusive symptom may be: lightning pains, failing vision from optic atrophy, double vision from paresis of ocular muscles, attacks of vomiting, tenesmus, unsteadiness in walking, painless joint disease, impotence, troubles with micturition, or some other less common complaint. In these the diagnosis rarely causes difficulty. A history of characteristic pains, or evidence of syphilis in the past, justifies the diagnosis of tabes on the symptoms alone. In almost all of these cases, moreover, unequivocal signs will be found which make the diagnosis certain. Two signs—the Argyll Robertson pupil and absence of the ankle-jerks or knee-jerks—are of supreme importance, for although one is often lacking, the absence of both in the kind of case we are discussing is rare. To one or both of these several of the following con-

firmatory signs are usually added : inequality or irregularity of the pupils, diminished sensibility of the skin on the nose, on the chest and feet, absence of pain on compressing the calf muscles, loss of vibration sense in the feet, muscular hypotonia, defective sense of position in the limbs and unsteadiness when the eyes are closed.

When the symptoms and signs are slight and few, or when suspicious signs are found during a routine examination, the diagnosis is sometimes difficult, and may require for its elucidation a careful inquiry into the history, an examination of the blood and cerebro-spinal fluid, and a meticulous investigation of the nervous system. These cases are discussed in the following paragraphs.

THE DIAGNOSIS OF EARLY TABES.—1. Since Westphal, some 60 years ago, described loss of the knee-jerks as an early sign of tabes, and established the existence of the pre-ataxic stage, the profession, apart from neurologists, has altered its views but little, and still hesitates to diagnose tabes while the knee-jerks are present. Consequently mistakes in diagnosis are common, and valuable years are lost before treatment begins. The diagnosis can and should be made when lightning pains are the only symptom. Pains with the characters already described occur in no other disease, and their presence calls for a careful investigation for evidence of past syphilis. In this first stage of tabes the diagnosis is founded on (1) characteristic pains; (2) evidence of syphilis in the past, obtained from the history or by examination of the blood and cerebro-spinal fluid (see p. 1184).

2. Only rarely need the diagnosis be made on these grounds alone, for in almost every patient with lightning pains careful examination will reveal confirmatory signs. The most important of these are sensory disturbances and alteration in the pupils. Hyperæsthesia to touch and temperature on the lower part of the trunk is very common, although few patients mention it until their memory is refreshed by careful interrogation. In a patient who has had syphilis and suffers from lightning pains, a clear demonstration of sensory impairment confined to the characteristic areas makes the diagnosis still more certain. Other signs to which a high value may be given are absence of pain when the calf muscles are compressed, loss of the vibration sense in the feet, and muscular hypotonia. Irregularities in the outline of the pupils without an obvious explanation, or pupils which react well to accommodation but sluggishly to light, are very strong evidence of past syphilis and should be duly appraised. This may be called the second stage of tabes in which the diagnosis is founded on (1) evidence of syphilis; (2) tabetic pains; (3) sensory disturbances with a characteristic distribution.

3. If to these sensory disturbances there is added an Argyll Robertson pupil, or if one ankle-jerk or knee-jerk is absent or definitely diminished when compared with its fellow, the diagnosis is established beyond doubt. This may be called the stage of the fully developed disease. The diagnosis rests on—(1) evidence of syphilis; (2) lightning pains; (3) characteristic sensory signs; (4) the Argyll Robertson pupil in one or both eyes; (5) absence of one or both ankle or knee-jerks, or a definite diminution in one of them.

Lightning pains indicate that the disease is active. In the absence of pains tabes would still be suggested by the combination of an Argyll Robertson pupil with an absent ankle or knee-jerk, or by the combination

of one or both of these signs with characteristic sensory loss. In such cases, however, it would be impossible to say whether the patient was suffering from tabes which was likely to progress, or whether the disease had been arrested in its earliest stage.

DIFFERENTIAL DIAGNOSIS.—*Peripheral neuritis.*—The signs common to both diseases are loss of reflexes, hypotonia, inco-ordination and sensory loss. Wasting, loss of power, changes in the electrical reactions of the muscles and tenderness of the calf muscles distinguish peripheral neuritis. A complete history and examination will usually reveal the cause of the neuritis, or disclose certain signs of tabes.

Friedreich's disease.—Loss of tendon reflexes and inco-ordination occur in both diseases, but the age of the patient, the family history, the speech defects, nystagmus and the deformities of the feet and spine make the diagnosis easy. Juvenile tabes is sometimes mistaken for Friedreich's disease.

Course and Prognosis.—In most instances the disease is well established before some serious symptom brings the patient under observation. For this reason it is usually impossible to determine the sequence and duration of the signs that are found, but if the onset of lightning pains and of ataxia are taken as landmarks, an idea of the extreme variability of the course of tabes in different cases will be obtained. In many patients the disease remains stationary in the earliest stage and causes no disability. In a larger number inco-ordination appears after a pre-ataxic stage of 10 or 20 years. Some become ataxic within five years of the onset of pains, a few within a year. Once ataxy appears, its rate of increase varies within wide limits. It may be so rapid that walking becomes impossible in a few weeks; it often increases very slowly, and only interferes seriously with walking after several years, and in a large number periods of increase in the ataxy alternate with long periods in which it is stationary or undergoes temporary amelioration.

The course of the other symptoms is equally variable. In general, irritative phenomena—pains and crises—tend to diminish, while the signs of destruction of sensory nerves—diminished sensation, hypotonia, etc.—increase. Ocular palsies are frequently of short duration, and bladder and rectal symptoms are often temporary. It is impossible to foretell how any given case will progress, but there seems to be some connection between the period which has elapsed since syphilis was contracted and the rate of evolution of the disease—the longer this period the more benign the course. If the symptoms have increased slowly in the past, the future course is likely to be slow, whereas cases of rapid onset often progress rapidly. When optic atrophy occurs blindness results almost invariably, and a proportion of these cases develop general paralysis of the insane.

The prognosis as to life is variable. Most tabetics die of intercurrent maladies or of some cardio-vascular complication, but life is constantly menaced by cystitis and ascending infection of the urinary tract.

Treatment.—This falls under three heads: treatment by anti-syphilitic remedies, general treatment, and treatment of individual symptoms.

ANTI-SYPHILITIC TREATMENT.—As soon as tabes is recognised or suspected in a patient who has had syphilis, thorough treatment by specific remedies should be given. Mercury is the most valuable drug. Several courses of daily inunctions should be given at intervals, until 60 inunctions have been applied. This is usually supplemented by injections of salvarsan. Between

the courses, which may be repeated at 6 monthly intervals, mercury should be taken by the mouth in a pill or mixture. Most observers agree that all forms of intraspinal therapy are useless.

GENERAL TREATMENT.—In early cases the patient should be encouraged to continue at his work and avocations, so far as this is consistent with the avoidance of undue mental or physical stress. Strict moderation in the use of alcohol and tobacco should be enjoined. Marriage should be forbidden. The diet should be generous, and efforts should be made to prevent the rapid loss of weight which is a feature of many cases. Strict attention to the bowels is necessary. In many tabetics the normal call to stool is not felt, and if regular efforts to open the bowels are not made, stasis develops readily. This should be treated by enemata or by glycerine suppositories. Purgatives should be used with discretion. They are of little use in stasis, and should not be given if there is any tendency to rectal incontinence, as this is always worst when the motions are soft. A change from purgatives to enemata or suppositories will often relieve this distressing symptom. The bladder should be emptied at regular intervals, regardless of the call which is apt to be less insistent than in normal persons. In general, rest in bed is to be deprecated. In some instances, however, where ataxy develops rapidly, it is advantageous, provided that daily treatment by massage and exercises is instituted at once.

TREATMENT OF SYMPTOMS.—*Pains.*—Of the many drugs that have been tried for the relief of pains the following either in single or in various combinations have been found useful: aspirin, phenacetin, antipyrin, exalgin, pyramidon, cannabis indica, colchicum, ammonium chloride and sodium salicylate. After one has lost its effect another will often give some relief. Morphine is the only drug that is certain in its action, but it cannot be allowed except on isolated occasions, when for some special purpose it is essential that the patient should be free from pain for a few hours. In no disease is the morphine habit more rapidly acquired or more difficult to break. External applications rarely do any good. Chloroform on lint sometimes gives relief. Hot baths, hot applications to the limbs and blisters to the spine are worthy of trial.

Intravenous injections of neo-salvarsan sometimes relieve the pains when other means have failed. The clothing should be warm, and sudden changes of temperature should be avoided. Residence in a warm country is an advantage. Attention to small details, such as the avoidance of constipation and abstinence from alcohol, often has a favourable effect.

Crises.—Gastric crises, like the pains, are very resistant to treatment. Chloretone in cachets containing 10 grains is often useful. It may be given twice or at most thrice in 24 hours. The effect of the drug should be watched carefully, as it sometimes produces alarming depression of the heart and respirations. When chloretone fails cerium oxalate and tincture of iodine should be tried. The use of morphine is not justified. Rectal crises are sometimes relieved by small doses of grey powder with opium or pulv. ipecac. co. The lower bowel should be emptied daily by enemata. In mild cases with morning diarrhoea an enema or a suppository should be used before the first evacuation. Thereafter the patient should try to resist the desire to defæcate, which soon passes away, and with a little training this troublesome symptom can usually be overcome. Laryngeal crises

though very alarming are practically never fatal. They are usually relieved at once by an inhalation of nitrite of amyl.

Bladder disturbances.—When there is any difficulty in passing water a mixture containing 5 minims of liq. strychninæ thrice daily will be found useful. When the bladder is imperfectly emptied the use of the catheter should not be delayed. Only too often neglect of this matter leads to death from pyelo-nephritis. It is well to remember that serious infections may run a painless course. Their presence must be sought for even when pain is absent. This entails an examination of the urine from time to time for evidence of inflammation in the urinary tract. If pus-cells are present in the urine, urotropine and acid sodium phosphate should be given by the mouth. If this does not remove them, the bladder should be irrigated daily until the urine becomes normal. True incontinence of urine is often diminished by 5 minim doses of tincture of belladonna thrice daily.

Ataxia.—Just as a normal person by practice and effort can learn to perform feats of balance and muscular co-ordination which are impossible for one untrained, so the tabetic by concentrating his attention on his movements can be taught to make greater use of his remaining powers. The results of appropriate re-educative treatment are often astonishing. It is no uncommon thing to see patients who had been confined to bed for months able to get about freely again. Permanency of the result is often a gratifying feature.

As long as the patient is able to get about the necessary re-education can be acquired, if he is taught to pay particular attention to each movement of his limbs, and to attempt to carry it out accurately. In more severe cases, and when the patient is confined to bed, re-education should be given along the lines devised by Frenkel. Constant supervision is necessary at first, and the treatment should begin in an institution, or under the supervision of a skilled attendant.

No remedy is of avail in checking the progress of optic atrophy. Subcutaneous injections of strychnine have been recommended.

The condition of the feet often requires attention. Corns should not be cut. Perforating ulcers should be curetted and dressed with a paste of iodine and starch. A cradle should be placed over the feet to prevent deformities, and over-extension of the knee-joint should be prevented by wearing a suitable splint.

Charcot's joints.—As soon as this condition is discovered, the patient should be put to rest, the joint immobilised, and those measures used which tend to relieve the œdema and the effusion into the joint; and if occasion demand, the joint should be aspirated. When the joint becomes dry it should be rested for a long period. For example, the patient with a Charcot's foot should use a peg stump for six months, when the condition will be found to have healed. The knee is a difficult joint to support, and the best treatment is excision of the joint, with the production of a stiff knee.

CONGENITAL SYPHILIS OF THE NERVOUS SYSTEM

Affections of the nervous system are much less frequent in congenital syphilis than in the acquired disease. Viewed broadly, the pathological

changes and the clinical manifestations are the same in both. Regarding the first, meningitis, endarteritis and gummata are common to both forms; but while central softening from arterial disease is characteristic of acquired syphilis, cortical cell atrophy and subsequent sclerosis are prominent features in congenital cases. As for the symptoms, mental defects, with convulsions and spastic weakness of the limbs, are typical of congenital syphilis in contrast to the hemiplegias and monoplegias, with or without convulsions, which occur in the acquired form. It is noteworthy that the combination of obvious visceral and integumental lesions, with parenchymatous degeneration of the nervous tissue, is very common in the congenital, but not in the acquired disease.

Symptoms.—Many syphilitic infants suffer from convulsions during the first two years of life and in many cases these are given as the cause of death. In those who survive, fits may continue or they may begin again towards the end of childhood. The latter is more common. The fits in some cases have all the aspects of idiopathic epilepsy, and may continue throughout life without the addition of any symptoms suggestive of local brain disease. In another group, convulsions are followed by symptoms of hemiplegia or of spastic diplegia. The same defects may appear apart from convulsions.

Mental impairment is one of the common features of the disease. Idiocy is rare. More often the defect is first noticed between the ages of 5 and 15 years. The child may merely cease to learn, and retain any acquirements he possess, or he may lose his memory and become slowly demented.

Vision is often defective as a sequel of atrophy of the optic nerve or of chorio-retinitis, and bilateral deafness is not uncommon. Affections of the remaining cranial nerves are rare.

Juvenile general paralysis appears most often between the ages of 10 and 17 years. It has been seen as early as the eighth, and as late as the thirtieth year. In some cases it results from congenital syphilis, in others from syphilis acquired in infancy or in childhood. The physical signs are the same as in the adult form. The mental symptoms, as might be expected, differ from those in adults, when mental decay sets in before the appearance of the instincts and passions which form the content of the delusions in older patients. A boy of 12, for example, is not likely to have delusions regarding his wealth or his intellectual capacity or his sexual powers, although he may well have grandiose ideas concerning his physical strength. Optic atrophy is very common in juvenile cases, and as in adults, signs of tabes are present in many cases.

Juvenile tabes presents the same features as in adults. It is important to remember that in rare instances, tabes in an adult owes its origin to congenital syphilis or to syphilis acquired in infancy.

The diagnosis of congenital syphilis of the nervous system rarely causes any difficulty, as the patients almost invariably present some of the stigmata of their malady.

Treatment by mercury should be carried out perseveringly. The results are disappointing.

DISSEMINATE SCLEROSIS

Ætiology.—Apart from syphilis, disseminate sclerosis is the commonest organic disease of the nervous system in English and Continental practice. It is said to be less frequent in America.

Cases have been recorded in which the disease was noticed after acute illnesses, such as scarlet fever, influenza and rheumatism; but it is probable that these simply made more prominent a condition already present. Febrile illnesses are always followed by increase in the symptoms, and many patients with disseminate sclerosis relate that they became much worse after an attack of influenza. There is no doubt that this so-called influenza has been in some instances at least a febrile phase of the disease itself. In the great majority of the cases there is nothing in the family or personal history to which the disease can be attributed. In one instance, confirmed by examination after death, it attacked a mother and her child, and a few similar cases, as well as the affection of several members of a family, have been recorded, but without pathological confirmation.

The onset is most frequent between the ages of 16 and 30, the sexes being affected equally. It is rare for the disease to begin after the age of 45.

The cause is still unknown, but the course of the disease as well as the inflammatory nature of the early lesions points to an infective origin, and recent research suggests that the causative agent is a specific transmissible virus, to wit, an organism resembling the *Spirochaeta pallida*. It is certain that syphilis plays no part in the ætiology.

Pathology.—As indicated by the name of the disease, the lesion consists in patches of sclerosis scattered like seeds throughout the substance of the brain and cord. They vary in size from microscopic areas to large plaques, which sometimes extend over the greater part of transverse sections of the cord or brain stem, or occupy still larger areas in the white matter of the brain. Under the microscope the older patches are found to contain proliferated neuroglia and nerve fibres which have lost their myelin sheaths. The axis cylinders in the sclerosed areas escape destruction for a long time. For this reason secondary degenerations do not occur in the spinal tracts, and sections of the cord between lesions at different levels present normal appearances. Ganglion cells are also spared; hence wasting of the muscles supplied by the affected segments is not a feature of the disease. In recent patches, œdema is present with infiltration by small lymphocyte-like cells, plasma cells and compound granular corpuscles around the blood vessels, especially in the adventitial sheath of the veins. It is highly probable that these inflammatory changes represent the initial lesion, and that the alterations in the nerves and in the neuroglia are secondary to them.

Symptoms.—The mode of onset as well as the course of the disease differs greatly from one case to another. This is explained by the nature of the early lesions, and by the extreme variations in their number and distribution. In the early stages the axis-cylinders in the diseased areas are not interrupted completely, but suffer partial and temporary impairment, which alters in intensity with the severity of vascular and other inflammatory changes in the tissues around them. Moreover, as the inflammation subsides in one patch a new one develops and produces a different set of symptoms. Again,

the first lesion may arise in any part of the brain or cord, and every conceivable combination of lesions and, therefore, of symptoms, is possible. Hence it is not surprising that the earliest symptoms are often slight and fleeting, or that they may first appear now in one part and now in another. In spite of this, however, certain symptoms and physical signs appear with remarkable regularity and render disseminate sclerosis, in the more advanced stages at least, one of the most distinctive and most easily recognised diseases of the nervous system.

In a typical case the most prominent features are—(1) spastic paraplegia or other signs of involvement of the pyramidal tracts; (2) tremor in the arms; (3) nystagmus; (4) pallor of the temporal half of the optic disc; (5) scanning speech. The triad formed by intention tremor, nystagmus and scanning speech is practically pathognomonic, and it is customary to give great prominence to these symptoms. It must be emphasised, however, that they are found together in a minority of the cases—say in 20 per cent.—and that some cases run their course without the appearance of any one of them.

MOTOR SYMPTOMS.—Weakness in the lower limbs is the symptom for which many patients first seek relief. Beginning with a feeling of heaviness or stiffness in one or both limbs, the weakness, which may be limited at first to one group of muscles, increases, in some uniformly, in a larger number with remissions or with periods of apparent recovery, until at last, after a time which varies from a few weeks to many years, it ends in severe spastic paraplegia. The physical signs are those of pyramidal lesions in general—increased tone in the muscles and exaggeration of the tendon reflexes, diminution or loss of the abdominal and cremasteric reflexes, and Babinski's plantar response. They are of extreme importance, for some or all of them may be present when the patient's complaints are still trivial, and they are found so constantly in all stages of the disease that the diagnosis of disseminate sclerosis is rarely made in their absence.

The paralysis can often be distinguished from that of other pyramidal affections by the variations in its severity from time to time, and by the occurrence of remissions or of apparent recovery, the improvement sometimes lasting for weeks or months, and, in rare cases, for many years. In most cases, moreover, examination will reveal some other sign—nystagmus, intention tremor, or pallor of the disk—which betrays the cause of the paralysis. In one large group of cases, however, the symptoms are those of a steadily increasing spastic paraplegia without remissions and without any indication, either in the physical signs or in the history, of extra-pyramidal disease. The gait may be but slightly altered, even when the tendon reflexes are greatly exaggerated and the plantar responses are “extensor.” Later, it becomes spastic or spastic and ataxic. Sometimes ataxy makes walking very difficult, when the power in the limbs is only slightly impaired. In the arms there is often loss of power associated with exaggeration of the tendon reflexes. In some cases the arms are affected before the lower limbs, when weakness or ataxy produces one of the commonest of the early symptoms—the “useless arm.”

TREMOR.—The characteristic tremor in the arms appears on voluntary movement only, and increases in rate and amplitude as the goal is approached. For these reasons it is called intention, volitional, or terminal tremor. It is sought for by causing the patient to touch his nose with the tip of one

finger. In its minimal form the tremor appears as two or three jerky movements of the finger just as the goal is attained, or the finger reaches the nose without any abnormal movement and then oscillates, so that it slips away from the nose again or depresses it several times before coming to rest. The tremor may be noticed first in writing or in performing other delicate movements, such as threading a needle. Later, the rate and amplitude of the movements increase, and the tremor, although still greatest at the end, appears almost as soon as a voluntary movement begins. In advanced cases it prevents all useful movements, and the patient is unable to do anything for himself. The arms are affected earliest and most often, but nodding of the head is common, and any part of the body may be affected. Beside intention tremor, other types of inco-ordination of the limbs are occasionally seen, such as those characteristic of lesions of the optic thalamus or of the mid-brain or of the cerebellum.

SENSORY SYMPTOMS.—*Subjective.*—Numbness and tingling in the extremities and alterations in the sensation of various parts are common complaints. They are often transient, and may be the only symptoms during the premonitory period. Severe pains are rare, but many patients complain of stiffness or of aching in the limbs and in the back.

Objective.—Severe sensory loss is not common, but careful examination will often reveal areas of skin in which sensation is impaired. Occasionally the loss is severe, and may show so sharp an upper level as to suggest the presence of a spinal tumour. In many cases the sense of position and passive movement in the limbs is seriously affected, in others loss of vibration sense is the only sensory sign. Like the other signs, the sensory disturbances often show considerable variations in extent and degree at different examinations.

OCULAR SYMPTOMS.—Attacks of *double vision* are frequent, and highly characteristic of the disease. Close interrogation, avoiding the leading question if possible, will often elicit an account of these attacks when the patient has not mentioned them at first, either because he has forgotten them, or because it does not occur to him that a symptom so remote or so transient can have any bearing on his present trouble. This diplopia is of the highest importance, because it is often the sole complaint when the patient seeks advice for the first time, and because its presence, or a history thereof, is often the deciding factor in the diagnosis of early cases with spinal symptoms. *Double vision* in a young person should always arouse the suspicion of disseminate sclerosis, and if it is associated with signs of pyramidal tract disease, the combination makes the diagnosis almost certain.

Strabismus is uncommon. Even when the patient is seen whilst complaining of double vision it is unusual to detect any limitation in the range of the ocular movements.

Ptoxis is rare.

Still rarer is "nystagmus of the lids," a rhythmical up-and-down movement of the lids which appears on testing for nystagmus. It is usually associated with ptoxis of the eyelids.

Nystagmus is present in more than half the cases, and is frequently an early sign. It is usually fine, rapid and horizontal, appearing only when the eyes are directed to the side. In some cases the eyes oscillate constantly whatever their position. Except in rare cases, there is no apparent movement of objects, even when the oscillations are of wide range.

Visual failure.—Diminution of visual acuity due to lesions in the optic nerves—*retrobulbar neuritis*—occurs sooner or later in nearly every case. As in the case of the other symptoms, it is subject to exacerbations and periods of improvement. In many cases, acute retrobulbar neuritis is the first alarming symptom of the disease. A young healthy person complains of rapidly increasing mistiness of vision, usually in one eye, sometimes in both or in one after the other, reaching its maximum in a few hours or days; this is often preceded or accompanied by pain about the orbit, which is increased on moving the eye. In the common unilateral case the signs are those of a lesion in one optic nerve; the pupil on the affected side is larger than its fellow; its direct reaction to light is impaired, but it contracts well consensually. Tests with a small object, preferably coloured, reveal a *central scotoma*. At the onset the disc is usually normal, but sometimes the inflammation reaches the nerve head, in which event the disc is blurred and swollen. Later the disc may be pale or normal. Rapid improvement of vision is the rule. Special tests may reveal a persistent slight loss of visual acuity, and a partial central scotoma, or, very rarely, a complete central scotoma. Subsequent acute attacks are common. In some cases the onset of visual failure is gradual. Usually the defect is slight, but it may be serious, although complete blindness never occurs. In these cases the disc is pale, especially in its temporal portion, and the field shows a central scotoma or narrowing at the periphery.

Papilledema in one eye is common and the swelling is usually slight. Rarely it is bilateral, and may be great enough to suggest the presence of a cerebral tumour.

MENTAL SYMPTOMS.—Defective memory and slight impairment of intellectual power are common. Some of the patients are morose and subject to fits of depression, but the majority are surprisingly cheerful, and do not seem to suffer mentally even when their physical state is most pitiable. In many cases there is considerable loss of emotional control, and ready laughter or weeping is fairly common. More often there is merely a tendency to laugh at trivial things. It is said that the mental changes sometimes resemble those of dementia præcox.

SPHINCTER DISTURBANCES.—In the later stages defective control of the bladder is almost constant. Transient attacks of frequency of micturition or of slight incontinence sometimes occur in the earliest stages. In rare cases, control over the rectal sphincter is lost.

OTHER SYMPTOMS.—Deafness, giddiness and tinnitus, sometimes with repeated vomiting, are common. Epileptiform convulsions are rare. As any part of the central nervous system may be affected, a patient with this disease may present the features of a lesion of any part of it. In most instances the distribution of the signs will indicate that the lesions are multiple; but sometimes, although the patches are numerous, the signs are those of a single lesion, say of the internal capsule, of the midbrain or of the cerebellum.

CEREBRO-SPINAL FLUID.—The colloidal gold test is often positive. In a few cases the number of cells is increased. Otherwise the fluid is usually normal.

Diagnosis.—In a typical case the combination of spastic weakness in the lower limbs with nystagmus, intention tremor and optic atrophy, with or without scanning speech, makes the diagnosis easy. Typical cases, however,

are few in number, indeed cases in which all the cardinal signs are pronounced are labelled "text-book type," and are regarded rather as curiosities. It must be emphasised that most patients, when seen for the first time, present a very different picture.

1. The commonest early complaint is of some motor or sensory disturbance, of rapid onset, that causes difficulty in using the hand or in walking. This suggests disseminate sclerosis, and leads to questions that may elicit an account of an earlier attack of some kind, *e.g.*, of diplopia, retrobulbar neuritis, numbness, tingling, weakness or difficulty in using the limbs, or sphincter disturbance. A young person with weakness or numbness of one or more limbs, and a history of similar transient phenomena in the past, or of rapid failure of vision or of double vision, with complete or partial recovery, almost certainly has disseminate sclerosis. The history alone gives the diagnosis. It is confirmed by the presence of even one certain sign of pyramidal tract disease, such as Babinski's plantar response, absence of the abdominal reflexes, or a definite inequality of skin or tendon reflexes on comparing the two sides. Pyramidal tract disease without obvious cause in a young patient is probably disseminate sclerosis. The classical signs—nystagmus, intention tremor and scanning speech may all be absent. Nystagmus or intention tremor is a very important sign in a patient with the history outlined above, but its absence is not significant. Defective sense of position is commoner than intention tremor in early cases. In the finger-to-nose test the patient misses his nose because he is not sure of the position of his finger. Often, two defects are revealed by this test: difficulty in finding the nose and a few jerky movements of the finger as it approaches the nose—a highly characteristic combination.

2. In some cases the signs are those of uncomplicated spastic paraplegia, without anything in the history or the present state to indicate disease of any structures other than the pyramidal tracts. In some of these a history of similar attacks in the past or of periods of improvement will give the clue to the nature of the paralysis. In a smaller number the paralysis is steadily progressive, and its cause is a matter of conjecture based on probability—spastic paraplegia coming on in a young adult is probably due to disseminate sclerosis—or is arrived at by the exclusion of other possible causes, particularly of syphilis and compression. In these cases, frequent examinations must be made for nystagmus, intention tremor and optic atrophy.

3. Defective vision is often the first symptom. Optic atrophy or a central scotoma in a young person is probably due to disseminate sclerosis; likewise failure of vision, with improvement or fluctuations in severity. When the onset has been gradual, a history can usually be obtained of the characteristic transient motor, sensory or sphincter troubles, and some sign of pyramidal tract disease is found to indicate the cause of the eye trouble. Further, disseminate sclerosis is by far the commonest ascertainable cause of acute retrobulbar neuritis; hence, rapid failure of vision in a young person, without the accompanying symptoms which would be present with other possible causes, such as cerebral tumour, is probably due to disseminate sclerosis. Occasionally, in acute cases, a history of symptoms and the presence of definite signs give proof of the cause; often there have been no extra-ocular symptoms, and the signs, though suspicious, are not unequivocal, *e.g.* sluggish

or slightly unequal abdominal reflexes, or a doubtful plantar response; often there are no symptoms or signs of extra-ocular disease, but later events prove the nature of the early eye trouble, thus, even fourteen years may elapse between the first attack of retrobulbar neuritis and the appearance of other symptoms of disseminate sclerosis.

4. To cover other modes of onset that vary with the site of the lesion, it is sufficient to remind the reader that, excepting cerebral tumour, disseminate sclerosis is the only common primary organic disease of the central nervous system. If a young person, free from syphilis, has unexplained organic nervous disease, disseminate sclerosis is the most likely cause.

Disseminate sclerosis has to be diagnosed from various diseases, of which we will consider the following:

Hysteria.—The serious mistake of attributing the early symptoms of this relentless disease to hysteria can be avoided by careful examination of the nervous system. Pallor of the disc, absence of the abdominal reflexes, or a distinct difference between them at corresponding points on opposite sides, unequal exaggeration of one or more of the tendon reflexes when compared with their fellows, Babinski's plantar response on one or both sides—any one of these signs alone would render a diagnosis of hysteria untenable.

Compression of the cord.—When the signs in disseminate sclerosis are purely spinal, the diagnosis from *spinal tumour* presents real difficulties. The first may be mistaken for the latter, when the paralysis increases steadily without remissions and is associated with sensory loss extending upwards to a definite level, while the reverse error may be made when the symptoms caused by a tumour are purely motor, or vary in intensity, or are associated with nystagmus.

Spinal caries may cause difficulty when paralysis appears before disease of the bone has been detected, and the same applies to new growths in the vertebral column. If the paralysis is due to compression, examination of the spinal fluid will usually reveal the loculation syndrome, and an X-ray of the spine will serve to distinguish disease of the vertebræ.

Friedreich's ataxy.—This may be suggested by the presence of ataxy in a young patient with disseminate sclerosis. The distinction can be made at once, for in the latter disease the tendon reflexes in the lower limbs are exaggerated, whereas they are lost early in Friedreich's disease.

Course and Prognosis.—Once the disease is established, a downhill course is the rule, and death usually occurs in a few years. In a fair number, life is prolonged for 10 or 15 years, and patients have been known to survive for 25 or 30 years. Remissions and periods of temporary improvement are common. Usually they are short, and the patient is considerably worse after each exacerbation; but sometimes a remission lasts for several years and raises the hope that the disease is arrested. In all but the very rarest instances, however, symptoms recur, and the disease pursues its course relentlessly. The outlook for life is best in older patients with signs of disease of the spinal cord alone. Death is often hastened by bed-sores and infection of the urinary tract.

Treatment.—No treatment is of avail in curing the disease. Arsenic appears to be the most useful drug. Iodide of potassium in small doses is of great service. Belladonna invariably improves the sphincter trouble.

Massage and passive movements of the spastic limbs are appreciated by the patients. They should avoid over-exertion, but should not be kept in bed so long as walking is possible.

SCHILDER'S DISEASE: ENCEPHALITIS PERIAXIALIS

Definition.—A malady characterised anatomically by a progressive and massive demyelination of the white centre of the cerebral hemispheres, proceeding from a single focus or from two symmetrical foci, and producing the clinical picture of progressively increasing failure of cerebral function, local at first, but advancing in terms of the functions of the contiguous regions which are next affected, by the spread of the disease from its original starting-point.

Ætiology.—Nothing is known of the essential cause of the disease, but from the nature of the lesions it seems probable that a local infection within the nervous system, of a spreading character, giving rise to an inflammatory reaction, and quickly followed by intense demyelination, is the fundamental cause. Many of the reported cases have occurred in childhood, even as early as the second year. The latest case was in the fifth decade of life. The sexes are equally affected.

Pathology.—The characteristic lesion consists of: (1) A primary demyelination and, later, destruction of the axis cylinders of the central white substances of the cerebral hemispheres, which till very late spares the subcortical zone of white fibres and the radial cortical fibres, and produces a translucent jelly-like appearance of the oval centres. (2) A very early and perhaps primary overgrowth of the neuroglia, forming a feltwork, which is particularly intense round the vessels. (3) A general infiltration of the white matter of the brain with round cells, all of which are of neuroglial origin, and most of which are engaged in the removal of altered myelin or in the formation of neuroglial fibres.

The process commences most commonly as a symmetrical patch of demyelination, in either occipital white centres, less frequently in both temporal white centres or in both prefrontal white centres, and spreads directly thence until the whole of the oval white centres become demyelinated. These present a very striking translucent, greyish or yellow-brown appearance. The corpus callosum is involved, and the demyelination spreads downwards through the crura into the brain stem. Sometimes, especially in the central regions, the disease starts on one side, and, after playing havoc with the white centre of one hemisphere, spreads across the corpus callosum into the other. Until the central demyelination is well-nigh complete, the subsulcal arcuate bands or white fibres and the cortex appear unaffected to the naked eye, and the resulting picture of a brain, normal on the surface, and on section with apparently normal cortex and intact subcortical white bands, but with the oval centre completely changed and translucent, is peculiar to this disease. Not unfrequently other patches of the disease may be scattered throughout the central nervous system. These have been found in the optic chiasma, in the cerebellar stalks, and in the white matter of the brain stem and of the cord. This scattered distribution and the prominence of demyelination bring Schilder's disease very close to disseminate sclerosis, and it has actually

been described as "disseminate sclerosis in childhood"; but the massiveness and mode of spread of the lesions, together with their distribution, with predilection for the brain and avoidance of the spinal cord, its incidence in childhood and its entirely different symptomatology, separate Schilder's disease sharply from disseminate sclerosis.

Symptoms.—The clinical aspect is precisely that which might be expected from a progressive destruction of cerebral function, spreading by contiguity from the initial seat of the disease. In many of the cases blindness—by which is meant blindness without any change in the optic discs and with pupils reacting normally to light—has been the first symptom, and is the result of the symmetrical demyelination of the occipital white matter. As the disease spreads forwards into the temporal regions, bilateral deafness appears; and, later, bilateral ataxy and astereognosis—due to parietal involvement, bilateral spastic paralysis—the result of central involvement, and complete amentia—due to callosal and prefrontal involvement, develop.

In those cases in which the initial seat of the disease is in the temporal, central or frontal regions, the first symptom to appear is obviously determined by the location, and the order of development of symptoms will be changed, but the mode of progress is the same in all. Where the disease starts on one side only, hemianopia or hemiplegia is the first symptom, and these are followed by the train of added signs produced by the extension of the disease into other regions. Complete mindlessness and paralysis always dominate the clinical picture in the end. The disease-process within the brain sometimes causes swelling with increase of intracranial pressure, and signs of the latter may appear in the form of headache, vomiting and papilloedema. Such cases are not common, and most of them have been regarded in life as cases of intracranial tumour. Fits are by no means uncommon. Sometimes they constitute the initial manifestation of the disease, and they may occur at any time during its course, and may be local or general. Fever is usually absent, but there may be irregular pyrexia and some of the more acute cases have been pyrexial throughout. The cerebro-spinal fluid is normal in the majority of the cases, but sometimes there is an increased protein content and a small excess of lymphocytes.

Diagnosis.—The onset with cerebral blindness or with bilateral deafness, followed by signs of progressive cerebral destruction, is so rare in any other disease as at once to suggest the diagnosis of Schilder's disease, indeed no less than two-thirds of the reported cases have shown this picture. When the disease begins unilaterally, and more particularly when headache, vomiting and papilloedema are present, the distinction from intracranial tumour is difficult or even impossible, for in both diseases the local commencement and the progressive destruction occur. In Schilder's disease, however, high-grade papilloedema is not met with, and consecutive optic atrophy does not occur. It should be borne in mind that any locally commencing progressive destruction of the brain may be an example of this malady.

Course and Prognosis.—In most cases Schilder's disease is regularly progressive to a fatal termination. In some, however, periods of stand-still have been noted, while in a few others marked improvement for a time has occurred, as the result of administration of mercury, arsenic and iodides. The duration has varied from 7 days to 36 months, with an average of 9 months.

Treatment.—Beyond the fact that mercury, arsenic and iodides have brought about temporary amelioration in some cases, no treatment is at present known that will influence the course of the disease.

HEREDITARY ATAXY

Under the name of “hereditary” or “familial” ataxy are gathered together several clinical types of disease, which have many features in common, and between which almost every variety of transitional type may be observed. The common features of these diseases may be here expressed:

ÆTIOLOGICALLY.—They tend to develop during childhood, but in some families the incidence is late in life, often being in the sixth decade. They are hereditary, and the heredity may be direct or indirect, or the disease may suddenly appear among many members of the same child-rank at a certain distance from a common progenitor. As with all hereditary diseases, isolated cases in which no heredity can be traced are common.

CLINICALLY.—They are characterised by a slow, clumsy ataxy, which in the eyes appears as nystagmus, and in the speech is expressed by staccato and explosive utterance, slurring, drawing and general lack of articulatory precision. In the trunk and limbs the ataxy is shown by clumsy unsteadiness, intention tremor, titubation and by involuntary movements, somewhat like those of chorea. Disturbances of sensibility, both objective and subjective, are conspicuous by their absence, and the sphincters are not affected. Signs of involvement of the pyramidal system in the form of the extensor response in the plantar reflex, contractures or spasticity are present.

PATHOLOGICALLY.—The morbid change consists in a primary neuronie degeneration, with secondary glial proliferation in the following systems: (1) in the afferent neurons, comprising the posterior columns of the spinal cord; (2) in the neurons of the direct cerebellar tract and of Gower's tract; (3) in the neurons of the cerebellum and its direct connections; (4) in the neurons of the pyramidal systems in the ascending frontal convolutions; (5) in the neurons of the retina. While all these morbid changes may co-exist in the same case, yet it is common for the degeneration to fall heavily upon some of these systems, while others relatively or entirely escape. For example, in the spinal form of Friedreich's disease, the degeneration is practically confined to the posterior columns and the spinal cerebellar tracts, whereas in the type of primary progressive cerebellar ataxy the degeneration is entirely confined to the cerebellum. And, again, in familial spastic paralysis the lesion is confined to the pyramidal system. All such pure types are rare; but combinations of these types make up the clinical and pathological entities of hereditary ataxy. Optic atrophy from degeneration of the retinal neurons is especially characteristic of Marie's ataxy; but it may occur in every other form of hereditary ataxy.

The following types of hereditary ataxy are sufficiently distinct to merit separate description, and with them is included familial spastic paralysis, as this latter condition seems naturally to complete a clinical and pathological series—(1) Friedreich's ataxy; (2) Marie's ataxy; (3) Sanger Brown's ataxy; (4) primary progressive cerebellar ataxy; (5) type of Dejerine and Thomas; (6) a type closely resembling disseminate sclerosis but familial in incidence; (7) familial spastic paralysis.

Many types exist which do not quite correspond with the usual descriptions of the above, and any transition between these types may exist. They may show striking peculiarities in the age incidence, in the clinical aspect, and in the course and prognosis of the malady. It is usual for the type to remain constant in the same family; but even to this rule there are notable exceptions, which prove the close relationship of these diseases. For example, in one family which came under my observation five children were affected, and of these four were very typical cases of Friedreich's disease, but the fifth was a typical case of Marie's ataxy.

FRIEDREICH'S ATAXY

In addition to the slow, clumsy ataxy, Friedreich's type is characterised by the absence of the knee-jerk and other deep reflexes, and by the presence of the extensor plantar response and of contractures, especially in the form of pes cavus, and by the presence of curvature of the spine in the later stages of the disease.

Ætiology.—The first signs of the disease usually appear in early childhood and before the sixth year; but symptoms may not be evident until a few years later. In a considerable number of cases, however, the onset is delayed until the time of puberty, while in a few examples the onset may be delayed until after the age of thirty years. As a rule the age incidence is approximately the same in each child-rank of the same family; but sometimes the phenomenon of "anticipation" is well marked, the disease appearing at an earlier age in each succeeding generation as a whole, or in successive children of the same parents. The disease is said to be slightly more common in males. Isolated cases in which no heredity can be traced are not rare; but the tendency to familial incidence is striking and characteristic. Indirect heredity is the most common, for the reason that the subjects of this disease are usually afflicted in childhood and incapacitated by the time adult life is reached, and that they therefore do not procreate. Transmission occurs both through the males and through the females. Direct heredity is, however, by no means so uncommon as has been supposed, and in one family under my observation the disease had been transmitted from father to son for seven generations.

Pathology.—Gowers considered that the malady was of an abiotrophic nature. He thought that the nerve elements which degenerate were hereditarily endowed with a much shortened period of vitality, after which they underwent a natural process of decay. The spinal cord is unusually small, and apparently this smallness may be congenital, and the posterior roots tend to be small, grey and poorly myelinated. The essential change is a primary degeneration of certain neurons in the dorsal column of the spinal cord, of the pyramidal tracts and of the spino-cerebellar tracts, both dorsal and ventral. This degeneration commences first in the periphery of the axon, which slowly dies back toward the nutrient nerve cell, as the branches of an aged tree tend to die back towards the trunk.

The degeneration of the dorsal columns is usually the earliest change, and remains the most prominent feature throughout. In the lumbo-sacral region degeneration is found in the whole of the dorsal columns, except the cornu-commissural zone and the fibres in the immediate vicinity of the dorsal

horn, but a certain proportion of the fibres of every region remain intact throughout the whole course of the disease. The degeneration of the fibres of the pyramidal tract appears later. It has its origin in the ascending frontal convolutions, where atrophy and disappearance of the giant pyramidal cells have been shown. But as the degeneration is a process of dying back towards the centre, it is always best marked in the lower part of the spinal cord, and is often not to be traced above the decussation of the pyramids.

The spino-cerebellar tracts are constantly degenerated, the direct cerebellar tract being the most seriously involved. The cells of 'Clarke's column,' from which the direct cerebellar tract takes origin, and around which the pyramidal tracts end, degenerate and disappear, as does also the network of collaterals which surrounds these cells. Consequent upon these degenerations, and secondary to them, well-marked neuroglial proliferation or sclerosis occurs, and this is most marked where the degeneration is most severe, usually in the dorsal columns, where it may be in such great excess, and arranged in such irregular whorls, that it was formerly regarded as the primary pathological change. The cerebellum may be normal, or it may show varying degrees of atrophy of Purkinje's cells, or of any other of its cell elements, and of the tracts connected therewith.

Symptoms.—The onset is always insidious, and physical signs of abnormality usually precede any complaint on the part of the patient or his relatives. The first symptoms generally appear between the sixth and the tenth year of childhood; but if a careful examination be made of the younger members of the families upon which Friedreich's disease is incident, physical signs of the disease, especially the extensor response in the plantar reflex, the retraction of the great toe and some degree of pes cavus may often be found before the sixth year. Not infrequently the onset of symptoms does not occur until puberty, and in some families it is delayed until after the age of 30 years.

Ataxy is always the first sign to appear, and this is shown by an awkwardness of gait and a tendency to stumble and fall readily. Sometimes it is obvious from the history, that the ataxy dates from the earliest years of infancy, when it is said that the child was never strong on his legs from the time of learning to walk, and that he could never run properly or join on equal terms with other children at play. As the disease progresses, the gait slowly becomes more irregular and clumsy, and acquires a reeling and staggering character which resembles somewhat that of an inebriated person. The patient walks with his feet upon a broad base, and staggers and reels from side to side; but, notwithstanding this, he keeps a fairly direct line of progression. He takes short steps which are unequal, and which are irregular in relation to the line of progression, and the movement of each foot as it is raised is poorly co-ordinated. There is never the undue excursion and noisy stamping of the feet which is so characteristic of the gait of tabetic patients. The inco-ordination of both legs and trunk becomes very obvious in turning quickly, or in rising quickly from a seat. On account of the important effect of inco-ordination of the trunk upon the gait, the ataxy of the lower limbs, which is so marked on walking, becomes less evident in movements of the legs performed when the patient is lying in bed.

Static ataxy is very marked, and this results from defective co-ordination of the muscles required to maintain a fixed position against external forces,

and especially the force of gravity. Thus in standing the body oscillates from side to side in slow and clumsy fashion, and coarse tremors of the head and trunk are constant features in advanced cases (titubation). There is consequently considerable difficulty in balancing the trunk upon the feet in standing. Sometimes Romberg's sign is present; but this is never so well marked as in tabes, and it is frequently entirely absent. The ataxy invades the upper extremities, as a rule, later than the legs. There is first clumsiness with the finer movements, and then little by little with all the movements. It closely resembles the ataxy due to gross disease of the cerebellum, and differs from that which occurs in tabes, and that irregular breaking of a movement towards the end of its accomplishment, which has been long termed "intention tremor," is frequently seen.

Very characteristic of the disease, and highly important in diagnosis, is the occurrence of irregular involuntary movements, which are often described as like those of chorea or of myoclonus. They differ entirely, however, from the movements of chorea, etc., in that they occur only when the limb or some of its segments are unsupported, for they depend upon a loss of synergy between the muscles which maintain the postural tone. In advanced cases such movements are constantly seen in the head and neck as nodding movements and tremors, and in the trunk as swaying instability, when the patient is sitting unsupported or standing. Similar ataxy and irregular movements affect the muscles of the eyes, of the face, tongue, larynx, etc., and the respiratory muscles. In the eyes they are seen as fine, regular nystagmus and as coarse, irregular jerkings, chiefly upon lateral deviation. There is no other disease in which ataxy of the facial muscles is so conspicuous for, on engaging the patient in conversation, all the facial muscles may be observed in irregular contraction. Perhaps some of the spontaneous involuntary movements of the face are truly choreic in nature, and are indicative of involvement of the corpus striatum. The ataxy of these muscles causes an invariable impairment of articulation, which gradually becomes indistinct, clumsy, drawn out and slurred. The syllables tend sometimes to be separated, adding a staccato element. Explosive utterance is almost constant, and from the irregularity of the respiratory movements short inspiratory whoops are not uncommon. Articulation thus closely resembles that of advanced disseminate sclerosis, the cause being identical in the two diseases, namely, interference with the cerebellar co-ordinatory mechanism of speech.

The strength of movements is at first little impaired; but as the disease advances and the pyramidal degeneration increases, the power is gradually lost in proportion to the degree of the pyramidal degeneration, which varies greatly in different cases. The lower extremities are affected first and most, and later the arms, and in severe cases at a late stage paralysis may be almost universal.

The condition of the muscular tone depends upon the relative degree of degeneration in the posterior roots and in the pyramidal tracts respectively, the former tending to abolish and the latter to increase it. As a rule the influence of the posterior root degeneration is preponderant and, therefore, the limbs are flaccid and hypotonic, but occasionally they are somewhat rigid. Contractures are the rule, but these are confined to the lower extremities. The most constant of these produces the deformity of the feet characteristic of Friedreich's disease, and known as "pes cavus." The great toe is

strongly retracted, the tarsus is pulled up, and the metatarsus is dropped and the plantar arch is increased. The outline of the inner border of the foot comes to resemble the letter Z, the tarsus, metatarsus and great toe forming the three limbs of the Z. Sensibility is but little affected; but in most cases minute examination reveals slight relative loss to touch, pain and temperature, most marked at the periphery of the limbs and diminishing upwards. Similarly there may be slight loss of sense of position in the limbs, with diminution of osseous sensibility to the slowly vibrating tuning-fork.

The ocular movements are almost always intact apart from the already described nystagmus. In rare instances strabismus, diplopia and ptosis have been recorded. In one family, which came under our observation, extreme slowness of the ocular movements occurred in three generations, all of whom were observed at the National Hospital. The pupils are not affected. Optic atrophy is a rare phenomenon in Friedreich's disease, yet it has been reported in quite a number of otherwise typical cases.

Mental symptoms are usually not conspicuous, but some of the patients are of poor mentality from the first, while others show a tendency to severe mental degeneration in the later stages of the disease. Emotional instability, irritability and outbursts of temper may occur.

Absence of the tendon reflexes is a most characteristic feature, and is often the first objective sign of the disease. When one considers, however, that the absence or presence of the tendon reflexes depends upon the relative degree of affection of the posterior columns upon the one hand, and upon the pyramidal degeneration upon the other, it is not surprising to find in cases where there is a major degeneration of the pyramidal tracts, that the knee-jerks may persist or even be brisk into the advanced stages of the disease. The abdominal reflexes gradually disappear. The plantar reflex is invariably an extensor response. The sphincters usually escape. The cerebro-spinal fluid presents no abnormality as regards cytology, albumin content or sugar reaction.

Spinal curvature is very common, and may reach a severe degree. It consists of a scoliosis of the dorsal region, and often with some kyphosis, and with a compensatory reverse lumbar curve. The cause of this deformity is probably the defect in the postural tone of the muscles, which occurs when the afferents subserving the function of postural tone, and which are contained in the spino-cerebellar tracts, are severed.

Diagnosis.—In uncomplicated cases the diagnosis is a matter of no great difficulty on account of the strikingly distinct nature of the symptoms. Friedreich's disease can hardly be mistaken for tabes since the history of heredity, the peculiar deformity of the feet and spine, the extensor response, the speech affection and the nature of the ataxy contrast strongly with the loss of pain sensibility and of deep sensibility, the pupillary changes, the sphincter trouble, the abnormal Wassermann reactions and the abnormal cytology of the cerebro-spinal fluid in tabes. The distinction from disseminate sclerosis presents more difficulty; but in this disease the onset never occurs in childhood, there is no heredity, the deep reflexes are never lost, and the spinal deformity does not occur.

Course and Prognosis.—The course of the disease is usually progressive in slow and irregular fashion, and the prognosis is therefore in every case serious; but the average duration of the disease is over 30 years, and in some cases it seems to have no tendency to shorten life. The prognosis is worse

and the course more rapid in those patients who have shown disability from the time of learning to walk. In some cases the disease appears to become arrested, as, for example, in one family which came under my observation, twelve members in three generations were affected with typical Friedreich's disease, yet none of them was incapacitated from following a normal life, and those that were deceased had all survived the age of 70 years. Similar examples have been recorded by Gowers. Intercurrent maladies, febrile illnesses and debilitating influences generally, may have a strong effect in hastening the advance of the disease, and bringing about a fatal termination. Confinement to bed from any cause whatever has a most derogatory influence upon the ataxy, and upon the capacity for walking. It is not an uncommon experience for a patient who is able to get about in comfort to be put to bed either for purposes of examination, of treatment or for illness, and permanently to lose his power of walking from the temporary deprivation of his usual exercise. It is therefore of great importance that these patients shall be kept off their legs as little as is possible. Cases in which the ataxy becomes extreme, or in which paralysis from pyramidal degeneration becomes severe necessarily become bedridden, and in this condition the patients may survive for many years. In other cases rapid increase of the symptoms of degeneration within the nervous system is followed immediately by drowsiness, asthenia and coma, and death occurs in that peculiar toxic state which is commonly the end result of all degenerative nervous diseases.

Treatment.—No treatment is known which specifically affects the malady. General tonic treatment, and all measures which improve the general health and mental well-being, often have a surprising effect in improving the ataxy. Re-educational training of the limbs and trunk in the form of Frenkel's exercises are most beneficial. Properly designed boots to ensure the most advantageous use of the deformed feet must be provided.

MARIE'S ATAXY

Under the name "hereditary cerebellar ataxy" Marie, in 1893, grouped together as a separate type certain cases which, so far as the nystagmus, speech and ataxy were concerned, exactly resembled cases of Friedreich's disease, but were characterised clinically by spasticity of the legs with an invariable increase of the knee-jerk, etc., and by the common occurrence of optic atrophy and by the occasional presence of the Argyll Robertson pupil. He showed that the incidence of the disease is at a later age than that of Friedreich's disease. He contended that the fundamental lesion causing this morbid entity was a progressive atrophy of the cerebellum, and that the spinal cord in these cases was either normal or only presented minor lesions.

Cases exactly corresponding to Marie's type are not uncommonly seen. It is certain, on the one hand, that the pathological anatomy of these cases is not confined mainly to the cerebellum as Marie argued, but that it closely resembles the pathological anatomy of Friedreich's type. And, on the other hand, it is equally certain that both Friedreich's and Marie's type may occur in members of the same family. It has been further contended that an onset in later years and after puberty occurs in this type; but while this may be the rule, some of the cases show symptoms from the first years of childhood.

SANGER BROWN'S ATAXY

This type, which is now commonly called "spino-cerebellar ataxy," is characterised anatomically by an outstanding primary degeneration of the spino-cerebellar tracts. Degeneration in the dorsal columns is present, but in less degree. The pyramidal tract is usually unaffected. The general clinical aspect of this type, as regards the slow, clumsy ataxy, the speech defects, and the involuntary movements, is exactly the same as in Friedreich's disease. The distinguishing features of the type are as follows: (1) The onset of the disease occurs after puberty, and may be delayed until late in life. In Sanger Brown's 25 cases in five generations of one family, the onset was between the seventeenth and the thirty-fifth year. In Neff's 13 cases in four generations, the onset always occurred about the age of 60 years. (2) Nystagmus is usually absent. (3) Ptosis, diplopia and extensive ocular paralysis may occur. (4) Optic atrophy is the rule. (5) Scoliosis does not occur. (6) The plantar reflexes are of the flexor type.

PRIMARY PROGRESSIVE CEREBELLAR ATAXY

In this type the characteristic pathological lesion is a degeneration of the cells of the cortex of the cerebellum and of the fibres connecting it with the central nuclei. The efferent cerebellar tracts are intact, as are also the afferent cerebellar tracts with the exception of the olivo-cerebellar fibres, which are markedly affected. The whole cerebellum becomes remarkably reduced in size. Clinically, this type is distinguished by the onset of ataxy of a cerebellar type shortly after middle life, but sometimes earlier. Nystagmus, affection of speech, ataxy and spontaneous involuntary movements, closely resembling those of Friedreich's type, dominate the clinical picture. Optic atrophy sometimes occurs. The reflexes are normal, and scoliosis and other deformities do not occur. The course of the disease is slowly progressive.

TYPE OF DEJERINE AND THOMAS; OLIVO-PONTO-CEREBELLAR ATROPHY

This malady, which shows many features in common with primary progressive cerebellar ataxy, was first described by Dejerine and Thomas, who showed that the pathological lesions consist in atrophy of the cerebellar cortex, of the bulbar olivary bodies, and of the grey substance and nuclei of the pons, while the middle peduncles of the cerebellum are completely, and the inferior peduncles partly, degenerated. This disease is neither familial nor hereditary, but it is here described on account of the similarity of its pathological and clinical features to the other types of hereditary ataxy. It commences late in life, and usually in the sixth decade, with clumsy ataxy of the limbs, marked ataxy of speech, intention tremors and spontaneous involuntary movements. Nystagmus may be well marked, or it may be absent. The reflexes are unaffected. The malady is a progressive one.

THE TYPE RESEMBLING DISSEMINATE SCLEROSIS

In this condition the symptomatology of disseminate sclerosis is closely imitated, and most of the cases which have been recorded have been described

as familial cases of disseminate sclerosis, as, for example, by Eichhorst. Several cases from a family in which three generations were affected, were shown by me before the International Medical Congress in London in 1913. The onset in my cases has been in early adult life, with a few exceptions of an onset in childhood. The clinical picture has been one of nystagmus, ataxy of speech, ataxy with intention tremors of the upper with spastic ataxy of the lower extremities, an extensor response in the plantar reflex and sphincter trouble. The retrobulbar neuritis and the exacerbations and remissions in the symptoms which are so characteristic of disseminate sclerosis, have not been noticed in these cases.

In some of the families which I have observed, sphincter trouble, loss of the abdominal reflexes and the extensor response in the plantar reflex have been entirely absent throughout, thus contrasting strongly with disseminate sclerosis, and coming somewhat to resemble the type of Dejerine and Thomas and that of primary cerebellar ataxy. When one considers that the elements of the nervous system which may be affected in the degeneration of hereditary ataxy are precisely those which are commonly affected in the lesions of disseminate sclerosis, it is not surprising that the clinical picture of the latter disease may be in some cases closely simulated by the former.

FAMILIAL SPASTIC PARALYSIS

This malady is here described with the hereditary ataxies, since it seems to fall naturally into the group of diseases in which primary degeneration of the pyramidal tracts is a usual anatomical feature, and of which a familial and hereditary incidence is the rule. Moreover, among the hereditary ataxies every grade of transition is seen to the type of pure familial spastic paraplegia. Whilst in the majority of the hereditary ataxies cerebellar, spinal and cerebral lesions coexist, yet there are the purely cerebellar and the purely spinal type; and the purely cerebral type, in the form of familial spastic paralysis, forms a natural end to the series.

Ætiology.—The disease is sometimes hereditary, but is more commonly familial and incident upon several children of the same parents. Sporadic cases are not very rare. The onset is gradual in early life, and usually occurs after the sixth year.

Pathology.—The pathological changes consist in a primary degeneration of the pyramidal neurons which apparently takes place in terms of the length; those supplying the lumbo-sacral region, being lower and longer, are earliest affected; those supplying the brain stem, being shortest, are the last to be affected. Degenerative changes in the neurons of the posterior columns of the spinal cord are often present, showing the transition to the pathological type of the hereditary ataxies.

Symptoms.—The clinical aspect consists in the slow development of spasticity and weakness, first and most in the legs, which gradually increases and progresses to the trunk and upper extremities, and involves the face last and least. The usual signs of pyramidal involvement are present in the loss of abdominal reflexes, increased deep reflexes and extensor type of plantar reflex. The malady is progressive, increasing to complete paralysis, and in its course contractures of the spastic muscles occur, that of the foot and leg producing some degree of pes cavus, while, above this, flexor contracture at

hip and knee is met with. Optic atrophy is by no means uncommon. Mental symptoms do not occur in uncomplicated cases, neither is epilepsy observed.

Diagnosis.—This malady is most easily confused with cerebral diplegia; but the latter disease appears much earlier, so soon after birth, in fact, as defective movement in the child can be ascertained. Further, cerebral diplegia is not a progressive disease in the majority of the cases, and it is often associated with mental deficiency and recurring convulsions.

PARALYSIS AGITANS

Synonym.—Parkinson's Disease.

Definition.—A progressive disease of insidious onset and slow course, usually occurring in the second half of life, and characterised by a peculiar stiffness of the muscles, which tends to fix the body in a certain posture, which can be changed less speedily than in health, and which gives rise to a distinctive facial expression, bodily attitude and gait. The stiffness is accompanied by weakness, and often by rhythmic tremors, which have earned for this malady the name "shaking palsy."

Ætiology.—Little is known of the causal factors of this malady. It is essentially a disease of the decline of life, and though in rare instances it is met with as early as the eighteenth year, the maximum incidence is from the fiftieth to the seventieth year. Men suffer twice as frequently as women. Heredity seems to play no part in the causation; but it is remarkable that longevity in one or both parents is common. Debilitating influences of any nature may be the immediate exciting causes of the appearance of symptoms. Overwork, mental shock and worry, and weakening diseases, such as influenza, and especially traumatism, are found in this connection. The latter not infrequently determines the limb in which the tremor first makes its appearance.

Pathology.—No naked-eye changes are to be found other than the vascular and degenerative changes which are common in senile conditions. The facts that tremors and rigidity, almost identical with those of this disease, may be met with in tumours involving the substantia nigra of the crura cerebri, two striking cases with autopsy having been under my own care, and still more importantly, the frequent appearance of a paralysis agitans-like end-result in lethargic encephalitis, where the subthalamic region and substantia nigra are conspicuously picked out by the lesions, make it probable almost to a certainty that the locus morbi of paralysis agitans is the basal ganglia. Gordon Holmes has found conspicuous cell degeneration in the substantia nigra in this disease, the pathogenesis of which must be considered to be a primary neuronc degeneration of the cells of the substantia nigra, and the condition one variety of extra-pyramidal paralysis.

Symptoms.—The onset is always insidious, and the muscular rigidity is almost always the first sign to appear. This rigidity affects the face, neck and trunk to a greater extent than the limbs, and when the limbs are affected then the proximal muscles present a greater degree of rigidity than do those of the periphery. The oncoming rigidity of the facial muscles does away with the usual play of the emotional movements in facial expres-

sion, and the face assumes a fixed, anxious and mask-like expression, with absence of the usual involuntary nictitation. The voice loses its inflexions, and becomes monotonous, from rigidity of the muscles of larynx, tongue and lips; but there is no other defect of articulation. Very striking is the effect of the rigidity of the muscles of the neck, for the patient carries his head and neck in one piece with his trunk as if he were a statue, never inclining or raising it in the customary expressive manner, and if he turn round to look at anything he tends to move the whole trunk round with the head. In looking sharply to one side the eyes move before the head, whereas, under normal circumstances, the coarse adjustment of this movement is done first by the neck muscles, and the fine adjustment subsequently by the eye muscles. The stiffness of the trunk muscles gives a stooping attitude with the head inclined forwards, while that of the upper extremities causes the shoulders to be rounded, and the arms carried with the elbow semiflexed, and pressed into the sides. The gait is highly characteristic in marked cases since, on account of rigidity of muscles, it is deprived of spring and suppleness; the patient, in the characteristic attitude above described, takes small gliding steps, displacing his centre of gravity as little as possible. If, by any circumstance, such as catching the feet against an unevenness of the ground, or a push, the centre of gravity is much displaced, the patient often has a difficulty in regaining it, and in moving to recover his centre of gravity is unable quite to catch it up, and so continues the movement of necessity until he fall or come in contact with some object by which he can arrest himself and restore his balance. This phenomenon is more often seen in advanced cases, and is known as "propulsion," "retropulsion" and "lateri-pulsion," according as the centre of gravity is displaced and the movement occurs in a forward, backward or sideways direction. Festination is the term used for the quickening of the pace sometimes seen in this attempt to overtake the displaced centre of gravity. In the hand the rigidity is greater in the interosseal muscles, and the hand therefore tends to assume the "interosseal position" with the fingers pressed together and the thumb adducted, the metacarpophalangeal joints being flexed, and the interphalangeal joints extended. From this rigidity of the hand the writing becomes small as well as tremulous, and the patient finds it difficult to write in a straight line. Muscular weakness always accompanies the rigidity and the tremors. It is slight until the late stages of the disease, when it may increase rapidly and render all useful movement impossible. On account of the rigidity and consequent slowness of movement, the sense of weakness which the patient experiences, is much greater than the actual weakness as tested by the dynamometer. Tremor is present in the majority of cases. It usually commences in the hand and forearm, and is most conspicuous in this situation; but it may be seen in the face, tongue, jaw, neck and feet, while, in rare cases, it may be universal. The nature of the tremor is peculiar, and is highly characteristic. It is a regular rhythmical contraction of the muscles, alternating in the opposing groups with a frequency of from four to seven oscillations per second with a range of from an $\frac{1}{4}$ th to $\frac{3}{4}$ th of an inch. Its rhythmic nature, its slowness and its coarse range distinguish it from other varieties of tremor. In the hand the characteristic movement of the tremor is the rolling together of the opposed thumb and fingers, cigarette-rolling, bread-crumbling or drum-tapping movement. There is nearly always in addition a peculiar pronator-supinator

tremor. The tremor is increased by excitement and by self-consciousness, and ceases during sleep. A highly characteristic feature of the tremor in about one-half of the cases is that it continues during repose, and is temporarily arrested by the execution of volitional movement. In the other half of the cases however the tremor appears or is increased on voluntary exertion, and tends to be less during repose. There seems to be an antagonism between the tremor and the rigidity, for in cases where the rigidity is very conspicuous the tremor is little marked or absent, and conversely, when tremor is universal or is of early onset, rigidity is a less noticeable feature. Moreover the tremor is always distributed where rigidity is least marked. Characteristic of this disease, as well as of all other Parkinsonian syndromes resulting from involvement of the substantia nigra, is a peculiar quick fluttering of the eyelids when these are gently closed, and which cannot be prevented voluntarily.

Other symptoms of the disease which are very commonly complained of are—(1) difficulty in turning over in bed, which is the obvious result of the rigidity of the trunk muscles; (2) flexion of the toes into the sole of the foot, so that they are trodden on, from spasm of the calf muscles; (3) pain of a dull aching character in the trunk and limbs, which is presumably produced by the long-continued traction of the rigid muscles upon their attachments; (4) abnormal sensations of heat and cold; and (5) hypersensitiveness to changes of temperature—the patient cannot bear to be near a fire nor yet in a cold room. Mental symptoms are conspicuous by their absence, except in the last stages of the malady, when profound physical asthenia overtakes both mind and body. The constant bodily discomfort, restlessness, sensations of fatigue, which the rigidity and the tremors engender, and the consciousness of a malady which is found only too soon to resist every effort to lessen or arrest it, often result in gloomy and lasting mental depression. Objective sensibility is unimpaired. The special senses and the cranial nerves are not affected. The sphincters and the reflexes are normal. Trophic changes in the periphery of the limbs, thinning and glossiness of the skin, with fluted nails and vasomotor disturbance, are common. Bed-sore is commonly met with in the late stages of the malady.

Diagnosis.—There are three points which can be surely relied upon to render the diagnosis of paralysis agitans certain in every case, namely—(1) the aspect of the patient when he is walking, when the fixed mournful expression, the stooping attitude with round shoulders, the elbows pressed into the side, and the hands carried across the abdomen in the interosseal position, the immobility of the head and neck, and the curious gliding gait which cannot fail immediately to arrest the observer's attention; (2) the rhythmic rolling tremor which is quite unlike any other form of tremor, and which often continues during rest; and (3) the absence of any of the usual signs of organic disease of the central nervous system. Difficulty may perhaps be experienced when the aspect is little marked, and the tremor is confined to some unusual situation, such as the face, tongue or neck; but, if the possibility of tremor in any situation being that of paralysis agitans be borne in mind, its rhythmic rolling nature will give the diagnosis. When paralysis agitans is confined to one side of the body, the appearance of the patient may superficially resemble that of hemiplegia; but in these cases the peculiar aspect of paralysis agitans is marked, and the organic signs of hemiplegia, such as the

extensor response in the plantar reflex, the increase in the deep reflexes, and the absence of the abdominal reflex upon the paretic side are not present. In senile tremor the rhythmic rolling quality is absent, and the aspect is not that of paralysis agitans. In post-hemiplegic tremor the organic signs of hemiplegia are present. Toxic tremor is irregular and never rhythmical, and is (mercurial tremor excepted) a fine tremor. The intention tremor of disseminate sclerosis, cerebellar disease and lesions of the red nucleus are so peculiar, and so widely different from the tremor of paralysis agitans, as to render confusion impossible.

The one clinical condition, which may so closely resemble paralysis agitans as to be superficially indistinguishable, is a not uncommon end-result in lethargic encephalitis, where from a lesion in the basal ganglia the same weakness, rigidity and tremors appear as occur in paralysis agitans. The distinction is not difficult, for the onset of lethargic encephalitis is usually acute, and the symptoms are definite. Moreover, the paralysis agitans-like syndrome of lethargic encephalitis sometimes shows a progressive amelioration, whereas paralysis agitans tends to a progressive downward course.

Course and Prognosis.—Paralysis agitans often begins in one limb, usually the upper, and spreads thence to the corresponding limb of the opposite, or to the other limb of the same side. In the latter case it has approximately a hemiplegic distribution, and it may remain for years much more evident upon one side of the body. The course is slowly progressive with variable rate. In some cases the malady may remain stationary for years, and this is more often seen in middle-aged subjects, before the disease has reached an incapacitating stage. Such arrest in the early stages is not often seen in young subjects, for in the latter the disease seems to take a more continuously downhill course. Real improvement in the symptoms is never seen. A fatal issue may occur in as short a time as two years; but this is exceptional, since paralysis agitans has little tendency to shorten life. The average duration is from 10 to 15 years, and since the major incidence of the disease is in the sixth decade of life it will be seen that many of the patients are of average longevity. Death may occur from intercurrent maladies, especially from bronchitis; but more commonly, after the lapse of many years, the patient becomes bedridden from increasing weakness and rigidity, and sinks into a condition of sleepy asthenia which is soon terminated by coma.

Treatment.—Paralysis agitans is one of the least tractable of maladies even as regards the relief of symptoms. Hygienic measures and tonic treatment, calculated to lessen the rapidity of the degenerative process, should be employed. Where there is much rigidity, gentle exercise, passive movements, massage and mild faradism are useful. Care should be taken to avoid the falls which the unstable gait is likely to engender, since these are often followed by a marked exacerbation of the symptoms. Pain is best treated with aspirin, and sleeplessness with a mixture of aspirin and small doses of barbitone (grs. ij to iij). Hyoscine, in doses of $\frac{2}{100}$ to $\frac{1}{100}$ of a grain, in chloroform water, given by the mouth thrice daily, sometimes gives great relief to the tremors and rigidity, and may be continued almost indefinitely without any ill effect. Morphine is badly borne. When the patient is bedridden great care must be taken with the skin, since the immobility of the trunk greatly increases the liability to the formation of bed-sores.

HEPATO-LENTICULAR DEGENERATION

Definition.—A progressive disease of the nervous system, often familial, characterised by involuntary movements, rigidity and hypertonicity, with contractures, without signs of pyramidal disease; and by dysarthria, dysphagia, emotionalism and progressive emaciation. Several closely related clinical forms of the disease bear distinctive names: *tetanoid chorea* (Gowers), *pseudosclerosis* (Westphal), *progressive lenticular degeneration* (Wilson), and *torsion spasm*, and *dystonia musculorum deformans* (Thomalla). Cirrhosis of the liver occurs in all forms. The Kayser-Fleischer zone of corneal pigmentation occurs in the first three forms, but has not yet been recorded in torsion spasm. The most constant nervous lesions are found in the corpus striatum.

Ætiology.—The disease often occurs in children of the same parents, but there is no evidence that it is congenital or hereditary. The age of onset has been as early as 7 years and as late as 26 years. The primary and essential lesion is in the liver; its cause is unknown. Syphilis is not a factor.

Pathology.—A multilobular cirrhosis, with "hobnail" liver, is always found after death. There is good evidence that the cirrhosis is not slowly progressive, but is the result of a number of attacks of acute hepatitis. The hepatitis has caused death in some members of affected families before nervous symptoms appeared. The nervous lesions are purely degenerative. In Wilson's cases, they were almost confined to the lenticular nucleus, especially the putamen. Every degree of degeneration was seen, from discoloration and sponginess of the nucleus in rapidly fatal cases, to shrinkage and atrophy, and even to complete disintegration and excavation of the ganglion. Later observers have described lesions in many other parts of the nervous system. The lesions are often most intense in the corpus striatum, but the noxious agent has no strictly selective action on any one anatomical group of ganglion cells, or on any limited area of the nervous system.

Symptoms.—In many cases there are no symptoms of disorder of the liver during life. In other cases an account is obtained of symptoms referable to acute hepatitis before the onset of nervous symptoms—attacks of diarrhoea and vomiting, pyrexia, jaundice, migrainous headaches, hæmatemesis and sometimes definite ascites.

The first nervous sign to appear is usually involuntary movement of the extremities, which may be of several kinds. In progressive lenticular degeneration, rhythmical tremors, increasing on voluntary movement, furnish the most common symptom. This is followed by rigidity of the face, the muscles of the neck, and later of the trunk, which rigidity increases steadily until the patient becomes helpless. The rigidity of the face and neck muscles gives rise to a peculiar expressionless appearance. Still later, extensive contractures, usually in the flexed position, in the upper and lower extremities, follow; but sometimes there is extensor contracture of the latter. During sleep the tremors cease, but the contractures do not relax. Dysarthria, of a slurring type, results from affection of the muscles of speech, and may end in complete anarthria. Progressive muscular weakness and general emaciation follow; and the patient becomes emotional, facile, docile and childish. There is no fibrillation or localised amyotrophy. The optic discs and pupillary reactions are normal. There is an absence of nystagmus, cerebellar

symptoms, and impairment of sensation. The reflexes are not altered, as in the case in pyramidal disease.

Prognosis.—The disease always ends fatally in a few months or years; the average duration is about 4 years.

Treatment.—None is known to have any effect upon the course of the disease.

JAMES COLLIER.

W. J. ADIE.

EPILEPSY

Definition.—A toxicopathic condition, characterised by suddenly occurring disturbances of cerebral function, which are prone to recur over long periods of time or even throughout life. The nature of the disturbance is probably in every case a loss of function, sometimes in a narrow region of the brain, at other times widely distributed. As the result of this loss of function, the lower centres of the nervous system may be released from control and may give rise to active phenomena, such as hallucinations, convulsions and mental disorder. In addition there may be gradually progressive cerebral and bodily deterioration in some cases.

Ætiology.—A familial tendency is often met with, but direct inheritance occurs much less frequently than would be expected, though epileptics often belong to families in which such maladies as migraine, hysteria, insanity, etc., are prevalent. Epilepsy may have its onset at any age in life from the day of birth to advanced old age. Its incidence is greater at certain periods of life, namely during the first two years, at the time of puberty, and at the commencement of the degenerative period of life round about the age of 50 years. Out of 1450 cases tabulated by Gowers, nearly one-third commenced before the age of 10, and three-fourths before the age 20. The incidence of the disease is almost equally upon the two sexes.

Exciting Causes.—In the majority of cases no cause whatever can be found for the occurrence of the first fit. When a direct cause is present, it is by far most frequently emotional excitement, in the form of sudden fear. Metabolic disturbances in early life, and especially rickets, are potent causes. Acute intoxications with absinthe, lead, bismuth and many other poisons may invoke epilepsy, as may also the poisons occurring in the specific fevers in childhood, in uræmia, cholæmia, hyperpiesia, puerperal eclampsia and Stokes-Adams's disease. And although in these intoxications the epileptic phenomena do not usually recur after the cause has disappeared, yet there is not one of the above-mentioned conditions which has not been followed by persistently recurring epilepsy. There seems, therefore, to be no adequate reason for separating these conditions under the terms "symptomatic epilepsy," "infantile convulsions," "febrile convulsions," "uræmic eclampsia," etc., as essentially differing from epilepsy; for they present phenomena of the same order which are clinically indistinguishable and which are almost certainly dependent upon the same order of causes as is epilepsy in general. Injury to the brain of any nature whatever, whether from violence from without or from disease within, may cause epilepsy. Traumatic cases in which the brain has been severely wounded are not associated with epilepsy in a greater percentage than 5 per cent. Cerebral tumours, agenesis, encephalitis, meningitis, cerebral syphilis and vascular

lesions give a higher percentage, which in children has been placed as high as 30 per cent. Again, there seems to be no useful purpose in separating the epilepsy which occurs in association with organic disease of the brain, as quite distinct from the epilepsy not so associated, under the term "organic epilepsy"; since every phenomenon which occurs in epilepsy is found in both these groups and the same treatment is appropriate for all.

Pathology.—No definite lesions of the brain nor of any other organs of the body have as yet been found to account for epilepsy. In severe degenerative and long-standing cases, widely-spread neuronc degeneration is found in the brain, but this is obviously a secondary and not a causal event, and is allied to the general degeneration of bodily nutrition which is met with in these cases.

The occurrence of epilepsy in the train of cerebral injury or disease led in past times to the belief that disease of the brain was the essential cause. It must be borne in mind, however, that epilepsy occurs only in a small proportion of these cases, and, taking epilepsy in general, the proportion in which any lesion of the brain has been found becomes infinitely small. Experimental work has shown that epilepsy cannot be produced in a susceptible lower animal by injury to the brain; but it can readily be induced by the introduction of a convulsant poison, such as picrotoxin, absinthe, lead and many others, into its anatomy, and it may also result by depriving the animal of some of its important metabolic organs, such as the thyroid and parathyroid glands. It is said even that animals "epilepticised" by absinthe may have epileptic progeny. It would appear that the same metabolic error is responsible for the appearance of epileptic manifestations in idiopathic epilepsy, in epilepsy from organic lesions of the brain, and in epilepsy which is symptomatic of other diseases, such as uræmia, rickets, etc., and that in organic lesions of the brain only those subjects develop epileptic manifestations who have a peculiar metabolism which makes them potential epileptics. Miller and Dendy have shown that in cats experimental lesions of the cerebrum which do not cause epilepsy can be rendered highly epileptogenous if metabolism be disturbed by the administration of a subminimal dose of a convulsant poison, such as absinthe, which would have no toxic effect at all upon the normal cat.

It seems probable that epilepsy results from some error of metabolism which allows of the development of a poison which has the effect of suddenly arresting cerebral function. In support of this hypothesis are the effects of poisons from without, such as lead, bismuth and absinthe, and of those developed within the body, as in the infectious fevers, and those occurring in metabolic dyscrasias, such as rickets, renal disease, hyperpiesia, hepatic disease, puerperal anaphylaxis, thyroid and pituitary disease, in producing manifestations in no way distinguishable from those of epilepsy.

The toxic effects of the serum of epileptic patients at the time of the attack has been investigated by Pagniez, Mouzon and Turpin, who have injected such serum into the circulation of animals, with the production of a series of convulsions, which lasted some half an hour and often ended fatally. No such convulsions occurred with the injection of serum from healthy persons.

Following the discovery of the poison choline in the cerebro-spinal fluid of epileptics by Donath, Sir F. Mott has shown the potency of this poison

in producing both convulsive and paralytic phenomena when applied in watery solution to the surface of the brain. It is at least possible that the liberation of some such poison locally from the degeneration of the tissues may be responsible for the epilepsy which results from local disease of the brain.

The leucopenia and the remarkable fall in blood-pressure which are known immediately to precede the epileptic attack have led Bossard to formulate "anaphylactic shock" as the immediate cause of the epileptic attack, and Tinel and Santanoise have shown in their patients the existence of alternating periods of sensitivity and immunity.

There are several clinical features of epilepsy which argue strongly in favour of a metabolic dyscrasia as its cause: (1) In the first place, there is the periodicity of epilepsy, with its often amazing regularity, the attacks occurring always at night or only in the day, or at regular intervals, or only at the menstrual epochs; and more strikingly still, those cases in which batches of fits occur at long intervals, sometimes many in one day—and during the long intervals nothing can induce the patient to have a fit. Such periodicity is more reasonably explained upon the grounds of a metabolic dyscrasia—now present, now absent—than on any hypothesis of disease, irritability, instability or functional derangement of the brain. (2) It is usual for the epileptic woman to have complete immunity from attacks during pregnancy, and this is intelligible on the grounds of the correction of a faulty metabolism in the mother by that of her foetus. (3) Status epilepticus is perhaps only explicable on the grounds of an acute toxic process. It closely resembles experimental convulsions from the exhibition of poisons, and is akin to uræmic and eclamptic convulsions, and is the commonest event by which epilepsy in itself causes death. It often arises in a patient who has had no fits for a very long time, and whose cerebral condition may, therefore, be deemed to be more stable than in the epileptic who has frequent fits. Sometimes over-exertion is the immediate cause, sometimes discontinuance of medicinal treatment by the bromides or luminal. Often no cause is apparent. The attacks begin and recur with increasing frequency and severity, in spite of the complete abrogation of cerebral function, and death is the common result in spite of any treatment that may be adopted.

I have in several cases of status epilepticus arrested the convulsions, restored the patient to consciousness and secured adequate nutrition, and yet death has occurred in a few days from cardiac failure with a rising temperature. Autopsy showed the most acute and intense fatty degeneration of the heart muscle—the invariable finding in fatal status epilepticus which has lasted any time. Such fatty degeneration is surely the result of an acute toxæmia which causes concomitantly the external manifestations of status epilepticus.

Hyperventilation.—It has long been known that the simple procedure of breathing as deeply as possible, as quickly as possible, for as long as possible, will in some subjects evoke the phenomena of tetany, which pass off after normal respiration has been resumed. Tetany is a condition closely allied to epilepsy. Recent researches have shown that similar hyperventilation will at once produce an epileptic fit in at least 40 per cent. of all the patients in an institution for epilepsy, and sometimes the proportion is much higher. So

apparently simple a disturbance of metabolism as the alteration of the oxygen, carbon dioxide and buffer-salt relations in the blood is a potent cause for the appearance of the epileptic attack. Further, Izod Bennett has recently attributed uræmic epilepsy to calcium shortage, which is the proved cause of many of the tetany conditions.

The nature of the change which occurs in the function of the brain at the moment of the attack is little known. It seems in all cases to start locally and may remain locally confined, in which case the manifestations will be confined to one function or one region of the body, and this is termed "local epilepsy" or "Jacksonian epilepsy." Or, it may spread from one point of origin to other parts of the brain, and it does so in terms of tissue continuity and of the representation of function on the cortex of the brain. For example, a convulsion commencing in one side of the face will spread to the arm, trunk and leg of the same side, in that order, because this is the order of representation of these parts of the body from below upwards in the ascending frontal gyrus. It may spread slowly when the resistance to the diffusion of the change is high, and may become arrested at any point. But when the resistance is low it may spread with lightning rapidity to all the regions of the cortex, sometimes not so fast but that it leaves the patient with a memory of the local commencement—"general epilepsy with a local aura or warning"; sometimes so fast that no memory of local signs remains—"general epilepsy without a warning." In the latter case, the side of the brain in which the change commences can always be determined by the direction of the conjugate deviation of the eyes when convulsion is present.

Formerly the nature of the change was deemed to be an abnormal excitation, or a spontaneous disordered release of energy from an unstable and irritable cerebral cortex. Hughlings Jackson first drew conspicuous attention to the very numerous negative phenomena which occur in epileptic seizures, and which often constitute the whole of the epileptic attack—such as the sudden loss of consciousness, the coma, the paralysis, the incontinence, and the extensor plantar reflexes—as signs of loss or arrest of cerebral function. More recently Hartenberg has advocated what is now the generally held conception that the initial event in the epileptic attack is cerebral inhibition or arrest of function, and that the positive events which occur in the epileptic attack—such as hallucinations, aura and convulsion—are release phenomena due to the action of lower centres in the absence of higher cerebral control. He brings forward the well-known fact that in animals in which the cerebral cortex has been ablated, convulsant poisons produce epileptic attacks of the same nature and just as readily as when the cortex is intact. In the human subject also one sees convulsion occur when disease has reduced the cerebral cortex to a presumably functionless condition. Hartenberg affirms that when the cerebral loss of function is slight and brief there is simple loss of consciousness for a moment, as in the common type of *petit mal*. When it is more severe, the patient falls in his attack. When still more severe, the lower centres are released from control and convulsion appears. He explains all the phenomena of epilepsy, both on the negative and on the positive side, on this hypothesis of inhibition of cerebral function. He defines epilepsy as a paroxysmal abolition of the higher function of the brain by arrest and not by excitation.

CLINICAL FEATURES OF THE EPILEPTIC ATTACK

PRODROMATA.—The circumstances which immediately precede the occurrence of an attack are of some importance. Speaking generally, it is uncommon for an attack to occur when the attention is fixed, or when some act is being performed, and from this it follows that the epileptic is relatively or absolutely free from attacks when at work and doing, and only in the rarest cases comes to harm or injury from accident. Some patients are able, by an effort of will in fixing attention, or by the performance of some vigorous action, to arrest attacks which have already begun.

Sometimes a change in the general condition of the patient may make him aware, or may acquaint those around him, that an attack is pending, and such signs of altered metabolism may herald an attack for from a couple of hours to a week. Headache, irritability, restlessness, euphoria, lethargy, somnolence, unusual appetite and a peculiar vacant look may all be met with in this connection.

Not infrequently the attack is preceded by paroxysmal manifestations which are in reality minute attacks, such as partial lapses in consciousness, a sense of strangeness, "dreamy state," jactitations of any of the muscles exactly resembling those seen in uræmia, slight auras, giddiness, sneezing and yawning.

DESCRIPTION OF THE ATTACKS.—The varieties of the epileptic attack are legion, and several types may occur in the same subject—indeed, it is unusual for fits to be always of the same type in one subject. They tend to vary both in degree and nature. They are usually divided into the less spectacular "minor" attacks, in which spasm is not a prominent feature; and "major" attacks, in which spasm is conspicuous. This distinction is purely artificial, for most patients have attacks of both varieties, and the two merge by insensible gradations the one into the other. Further, the minor attack often is the initial manifestation of the major attack.

The following description will serve to illustrate the more definite manifestation of epileptic attacks:

1. *Simple jactitation.*—Single twitching of individual muscles or groups of muscles, occurring, now in one part of the body, now in another, are seen in the majority of epileptics at some time or other. They are conspicuous in the convulsions of childhood, where they often constitute the chief clinical feature. They are well known as the "carphology," or "subsultus tendinum," of uræmic and eclamptic attacks, and in the "typhoid state." They may be not infrequently noticed in the epileptic person when he is otherwise well, and engaged perhaps in conversation or other occupation. Gowers emphasised epileptic twitching as a prodroma of an oncoming severe attack; but while in some instances this is undoubtedly true, yet it frequently occurs when no attack follows. It has been called "epileptic myoclonus."

2. *Simple loss of consciousness.*—In this, the commonest of all minor phenomena, there is a simple break in the continuity of consciousness. The train of thought and action is suddenly arrested for a few seconds, and there is a sudden stillness of posture and facial expression which attracts the attention of a witness. The face may show sudden pallor, a vacant expres-

sign, and curious fixity of the eyes, with large pupils. The patient does not fall, or move, or drop anything that he is holding. In a few seconds the attack is over, leaving the patient unable to describe what has happened, perhaps a little confused for some seconds, sometimes emotional and even hysterical. More often he continues what he was about as if nothing had happened. Such attacks sometimes occur very frequently, even hundreds in a day. They are characteristic of *pyknolepsy*, in which the prognosis is absolutely good, and also of a form of epilepsy in which rapid mental degeneration occurs and in which the prognosis is equally bad. Further, they may occur in organic disease of the brain.

3. *Simple loss of consciousness with falling*.—The patient suddenly falls, without warning, in the extended position, and almost always prone, so that his head reaches the ground first, and his forehead receives the bruise. He regains consciousness immediately, and picks himself up as if nothing had happened. It is not uncommon to see the forehead one region of scars, as the result of repeated falls; to prevent these a pneumatic protector should be worn. This form gave rise among the ancients to the name "falling sickness," or "*morbus caducens*." In another form of this type the head, or the head and trunk, alone are affected. The patient does not fall, but simply drops the head forward—"nodding spasm," or "*spasmus nutans*"; or he drops the head and bends the trunk forward—"salaam spasm."

4. *Simple loss of consciousness with slight spasm*.—This forms a gradation from the above types to the definitely convulsive seizures. The spasm is seen as conjugate deviation of the eyes, and perhaps of the head also, or it takes the form of laryngeal and respiratory action, giving rise to a groaning noise, or may involve any part of the musculature.

5. *Local fits*.—First explained by Hughlings Jackson, these events are known by the name "Jacksonian epilepsy," and this term has unfortunately become coupled with three glaring errors of conception which were never in the mind of that brilliant pioneer. These are: (1) That Jacksonian epilepsy is distinct from epilepsy in general. Actually it is simply a variety of epilepsy. (2) That Jacksonian epilepsy is always the result of local disease of the brain. The truth is that every known form of epilepsy may result from local lesion of the brain, and that local epilepsy also occurs in this connection, but that in the vast majority of cases of local epilepsy there is no local disease of the brain. (3) That Jacksonian epilepsy consists of local convulsion. Whereas it may consist of phenomena involving every single function represented in the brain.

The local fit is determined by the local commencement of the disorder of function, and by a relatively high resistance to the spread of the disturbance in the surrounding regions of the brain. And since loss of consciousness is attributable to wide-spreading loss of function, it follows that local fits are usually associated with no loss and but little impairment of consciousness. But it must be remembered that there is great tendency for the cortical disorder to spread, and that almost every case of local fits will at times exhibit fits which, commencing locally, become general, with loss of consciousness. The nature of the local fit will be determined by the region of its origin, and may take as many forms as there are functions localised in the cortex of the brain.

Psychic fits.—These may take the form of peculiar mental states, of

instantaneous onset, remembered afterwards sometimes in exquisite detail, sometimes only in vague character. Emotional conditions of fear or horror, which may cause the patient to attempt with violence to escape from his surroundings—"cursive" epilepsy—may occur. Or, the attacks may take the form of a sudden feeling of misery, or an intense sense of personal wrongdoing, a sense of intense familiarity in surroundings which are unfamiliar, a sudden sense of strangeness, as in a patient whose fit was "suddenly seeming to be somewhere else," a sense of euphoria or of intense mental energy, a dreamy state, often associated with smacking of the lips and champing or swallowing movements, which often has a pleasurable emotional tone. Again, the psychic fit may take the form of a highly complex and detailed hallucination, as in a patient of mine who suddenly found himself approaching a level railway-crossing in a picturesque village in high sunlight. Out of a little guard-house on the farther side came a woman dressed in the conical beaver hat and scarlet cloak of the Welsh national dress, who greeted him with a smile. He hastened forward to meet her, but found the gates rapidly closing upon him. As they closed, but before they touched him, he lost consciousness. In this case the hallucination was always the same in every detail in each fit. The historical visions of the saints have often been claimed as epileptic phenomena, and in some cases at least on reasonable grounds.

Visual fits.—These may take the form of negative phenomena, such as dimness of vision, complete darkness or hemianopia, or of positive effects, such as flashes of light, scintillating stars or balls of fire, or of both together in the form of blindness with flashes of light. In the last case they may closely resemble the visual phenomena of migraine, and are not infrequently caused by a local lesion of the occipital region. Complex visual hallucinations may occur.

Auditory fits.—The hallucinations of sound may be of any nature—hissing, booming and elaborate musical sensations, as of bells, being common. There is usually a sense of coincident deafness or "far away" hearing, which passes off with or soon after the sound.

In one case the fits could always be produced by sounding the hallucination note upon the open diapason of an organ. No other note or sound produced the fit. (Such directly excited fits, though very rare, are well known in connection with olfactory, visual, auditory and common sensory stimulation, and have been termed "reflex epilepsy.")

Olfactory and gustatory fits.—These hallucinations are always described as of "flavour," usually unpleasant. Very often, movements of the lips, tongue and jaw, or swallowing movements are present, and the dreamy state already referred to may be associated. From the location of the functions of smell and taste in the cortex of the uncinate gyri, and from the common occurrence of fits of this character in lesions of these convolutions, this type of fit is often referred to as the "uncinate fit."

Sensory fits.—These hallucinations may have their seat of commencement in any part of the body. They may remain local, but more commonly they spread from the point of origin in terms of the local representation of the body in the cerebral cortex, and usually from the periphery towards the trunk and head, but a sensory fit may spread to the extreme periphery first. For example, commencing in the fingers, it may spread up the arm to the head, or on reaching the shoulder it may invade trunk and leg before ascend-

ing to the head. It may be bilateral, confined to the anterior or posterior aspect of the body.

The sensation may be described as "numbness," "tingling," "pins and needles," "vibration," "rushing," "as if the limb were withering," much more rarely actual pain. Sometimes the sensation is indescribable. The sensory attacks have their origin in a local disturbance of the parietal region of the cortex, and may indicate the presence of an organic lesion in that region. They may be accompanied or followed by temporary loss of sensibility, in the form of astereognosis, loss of sense of position, or anæsthesia.

Another group of sensory fits for which it is impossible to give any definite cerebral localisation at present, is that of the so-called visceral auras, which are mainly referred to the distribution of the vagus nerve. Such are the very commonly occurring "epigastric" sensation, and sensations of choking, dyspnœa, nausea and cardiac sensations.

It is quite possible that the sudden feelings of malaise or of faintness which may constitute the main feature of some epileptic attacks are expressions of the sudden lowering of blood-pressure which is known immediately to precede the epileptic attack.

Disturbances in the realm of the vestibular nerve are very common indications of epilepsy. Sudden giddiness may be the sole indication of epilepsy, and is perhaps the most common initial event in major attacks. It may be indicative of the sudden fall of blood-pressure, or the feeling of rotation may be consequent upon early spasm causing conjugate deviation of the eyes. When the sensation is that of falling, or of being wafted away, there must be some essential disturbance of the nervous mechanism of orientation.

It must be carefully borne in mind that all the phenomena which have been described above may occur as isolated events and so constitute the epileptic attack. Often, however, the disturbance of the cortex spreads widely, involving general convulsion and loss of consciousness; but the initial phenomena are remembered by the patient as the "warning" of the attack and have from ancient times been termed "auras," when preceding general convulsion. In reality, they constitute the essential part of the attack as showing the region of the brain in which the disturbance starts, and in every patient who has such "warnings" preceding his severe attacks, the warnings occur at times by themselves without any such sequel.

Motor fits (simple paralysis).—This is the rarest of all forms of the epileptic attack. It consists in a sudden inability, relative or complete, to use a limb or one side of the body or the whole voluntary musculature, with no preceding convulsion. There are the usual signs of cerebral paralysis—at first flaccidity with a tendency for the jerks to fail; a few moments later increased jerks, with absent trunk reflexes and extensor plantar reflexes, all of which signs soon disappear. It may occur as an isolated phenomenon. More often a slight "minor" attack or a local sensory attack accompanies the onset of the paralysis. Sometimes such an attack may result from local disease of the brain. Gowers cites four examples which he observed, and I have treated two characteristic cases. Such attacks when involving the right face or right side of the body may occasion aphasia, or the aphasia may occur alone as the attack of simple paralysis. Such attacks of simple paralysis

without convulsion are well known in uræmia, hyperpiesia, metallic poisoning and general paralysis of the insane.

Local convulsion.—The spasm may commence in any part of the voluntary musculature, and may remain very narrowly confined throughout the fit or may spread in every degree to involve a whole limb, or one-half of the body, or to become general. It never affects the muscles of one eyeball alone, but the spasm is in terms of conjugate deviation of both eyeballs in one direction. The same rule applies when the neck is affected, for the head is then either rotated to one side or extended or flexed on the chest. With the other bilaterally associated muscles it is different, for the tongue is affected on one side only, as is also the face, and I have many times witnessed local fits in the muscles of the abdominal wall strictly limited by the middle line. The onset is with tonic spasm, which after a little while gives place to broken or clonic spasm, becoming more and more intermittent and finally ceasing. In some cases, but by no means in all, the convulsion leaves varying degrees of weakness in the affected muscles—Todd's paralysis or post-epileptic paralysis, with transient signs of loss of function of the pyramidal system, such as loss of trunk reflexes, increase of jerks, and extensor plantar reflexes. This paralysis was explained by Todd as due to exhaustion of the cerebral cortex from the violence of convulsion, and he was followed by Hughlings Jackson who surmised an exhaustion of the pyramidal system by which the convulsion was exteriorised. Such an explanation is, however, impossible, from the fact that a patient after a severe and long-lasting convulsion will often show no trace of paralysis, whereas another patient with a transient slight spasm of a limb may show severe paralysis lasting many hours. Hartenberg's explanation, that it is the local incidence of the cause of epilepsy upon the motor region producing inhibition, is much more probable. In other words, when the epileptic disturbance starts in the motor cortex there will be local inhibition and, therefore, less convulsion and more paralysis; whereas if the disturbance spreads to the motor function from elsewhere there will be no local inhibition and, therefore, more convulsion and no paralysis.

Epileptic spasm usually puts the hand in the position of extension at the interphalangeal joints, flexion and abduction at the metacarpo-phalangeal joints, flexion at wrist and elbow, and adduction at the shoulder. The feet are dropped and inturned, with extension at the knee and hip. Usually the trunk is in opisthotonus.

The sequence of tonic spasm at first, followed by clonic spasm, though usual in epilepsy, is not invariable. Purely tonic fits may occur with no clonic spasm, the tonic spasm remitting suddenly. Such fits are usually of slight severity and duration, and are almost always general and very rarely local.

On the other hand, the spasm may be clonic only. The simple jactitation already described may be taken as a simple clonic fit. Local fits, especially of the face and of the hand, may be purely clonic. Again, some of the most severe of all general epileptic convulsions are clonic throughout so far as the limb and trunk musculature is concerned, but some tonic conjugate deviation of eyes and head is usual.

Loss of consciousness in local fits.—This seems to depend upon the extent of the cortex involved. With narrowly confined fits there may be no

impairment at all, as in local convulsion of the face or hand, or as in a patient who vividly described to me a slow visual fit as it was occurring. When the fit spreads, consciousness is usually impaired, and when lost, it is lost late in the fit. For example, it is usual for a convulsion which spreads to one-half of the body to cause some impairment, and if it involves both sides generally consciousness is always lost.

General convulsive fits (haut or grand mal).—The general convulsive seizure in epilepsy does not differ from the local manifestations just described in any essential of causation and pathology, but simply in degree—as regards severity of manifestations, rapidity of spread to all regions of the brain, and rapidity of loss of consciousness. There is good reason for believing that every major attack has a local commencement in some region of the brain, and that it is in reality a local fit which rapidly becomes general. When such an attack commences with a local aura there is proof positive of local commencement. When it commences with conjugate deviation of head and eyes to one side, this is certain indication that the disturbance commences in the opposite hemisphere. When the spread of the disturbance is so rapid as to cause instant loss of consciousness there is no memory to retain the initial event of the attack. The seizure may begin with any of the local manifestations above described, the epigastric aura and giddiness being two of the most frequent. Or the patient may be only aware of his attacks from the condition in which he finds himself after their occurrence. The tonic spasm commences with conjugate deviation of both eyes to one side, followed by rotation of the head to the same side. The blood-pressure falls, the countenance is for a moment pallid, the eyes widely open, the pupils dilated, the corneæ insensitve. The march of the tonic spasm usually causes head retraction and opisthotonus; the upper extremities are stiff in flexion and adduction, the lower extremities in extension. If standing, the patient falls usually backwards, but the conjugate deviation of head and eyes may bring his face to the ground first. The respiratory muscles and larynx, going into spasm, produce the epileptic “cry,” and the respiratory movements being no longer possible the face darkens with the asphyxia, and the sphincters may relax, with the evacuation of bowel or bladder. The protrusor spasm of the tongue and the closing spasm of the jaw may cause the tongue to be bitten. After the tonic spasm has lasted some seconds and perhaps has produced such a degree of asphyxia as seems hardly compatible with survival, it begins to break into a series of sudden shock-like, jerky movements—the clonic spasm—which continue for some seconds, becoming less regular and occurring at longer intervals until, with a final jerk, the muscles become perfectly limp. Meanwhile the relaxation of the respiratory and laryngeal spasm have allowed the respiratory movements to return and to churn up the saliva, often bloodstained, which escapes at the nose and mouth in the form of froth. At the end of the attack there is complete and unrousable loss of consciousness, the pupils are dilated and insensitive to light, the corneal reflexes absent, the knee-jerks absent, and the plantar reflexes extensor in type. In a short time the knee-jerks return, the plantar reflexes return to the normal, and consciousness returns. Usually the patient is dazed, feels ill, has marked headache, and if left to himself soon sleeps heavily for some hours. It must be noted that the general convulsive attack almost always leaves the patient face downwards, so that he has drowned in a

puddle an inch deep and has been asphyxiated by his own pillow. The latter event is by very far the commonest way the epileptic meets his death from accident in a fit.

The epileptic cry.—There are two quite different sounds that may occur at the commencement of an epileptic attack. The one is a natural, conscious cry of terror at the advent, as in the patient who alternated piercing screams with "It is coming! It is coming!" before the convulsion commenced. It is curious how rarely any memory of such cries or utterances remains with the patient. The other is the epileptic cry proper—a weird, unearthly, hollow sound, produced by inspiratory spasm drawing air over the nearly closed vocal cords. This cry occurs in a minority even of severe cases, for the obvious reason that it is determined by a particular march of the spasm. If the inspiratory spasm occur before the larynx has gone into spasm or after it is in spasm, there can be no laryngeal noise, but only the commonly witnessed pharyngeal and buccal grunting and gurgling. The spasm must be so timed that the inspiratory spasm must occur as the larynx is closing, and this only obtains in a minority of the cases.

Tongue-biting.—Some patients always bite the tongue, others never, and some now and again. The tongue is always bitten at the side and some way from the tip, because it is deviated to one side in the spasm and its thicker part brought between the molar teeth. The same side is always bitten. The tongue cannot be bitten unless protrusor spasm occur either before the jaw has gone into tonic spasm or after it has broken into clonic spasm. If any other march of spasm occur, the tongue escapes. It is remarkable how little scarring occurs even from severe and repeated tongue-biting unless a piece is bitten clean out. It should never be used as evidence for or against epilepsy for this reason, and because it was readily produced artificially by those wishing to avoid military service.

Incontinence.—Though common, incontinence is by no means the rule even in severe attacks. More often it is the urine alone that is evacuated, much more seldom the bowel alone, still more rarely both.

Secondary events.—The degree of asphyxia during the attack may be severe, and blood vessels may give way under the stress, with the production of surface ecchymoses or deep hæmorrhages, including cerebral hæmorrhage. The spasm is powerful and may give rise to much subsequent aching, as if the patient had been beaten all over. It may dislocate joints, rupture muscles and even break bones. A dislocation once produced in a fit always recurs with subsequent fits.

Duration of epileptic attacks.—Two minutes may be given as an outside time-limit for the duration of an individual attack, from its commencement to the end of the active phenomena, and in convulsive attacks to the end of the spasm. Usually the time is much shorter than this, and often is a few seconds only. Sometimes attacks are described as of much longer duration. When analysed, such attacks will be found to be a series of attacks with very short intervals, or slight attacks with post-epileptic functional spasm, or hysterical attacks.

Conditions after attacks.—The epileptic fit may leave no after-effects whatever, even though it be severe, but this is unusual. On the other hand, even the slightest attacks may cause conspicuous sequels. Sleep and headache are very common, especially following convulsive

attacks, and they may be alternative effects, in that if sleep occur there is no headache, but if it be prevented there is severe headache. The post-epileptic paralysis of Todd has already been described, and also the aphasia which may follow right-sided attacks. The mental state is usually affected by the attack, and returns to the normal—sometimes quickly, sometimes slowly. Commonly the patient is dull and dazed, speaking at random, inceptive, irritable, and does not fully recognise his surroundings. During this state of impaired consciousness he may pass into a condition of mental automatism, in which various acts are performed in a conscious manner but of which no recollection is afterwards retained. One patient always prepared for bed after her minor attacks, and proceeded to undress in the stalls of a theatre. The acts performed during post-epileptic automatism may have a true relation to the life and mentality of the patient. He may do spiteful and criminal acts to those he dislikes. This fact has an important bearing as regards the criminal responsibility of the epileptic. In other cases a patient after recovering from the epileptic fit passes at once into a state of hysterical convulsion. Both these post-epileptic conditions occur commonly after minor attacks, but they may also occur after major fits; they seldom occur when convulsion has been severe.

Vomiting may occur after any type of epileptic fit, but it is most often met with after a convulsive attack. As it occurs during the period of unconsciousness, there is some danger of the vomited material being drawn into the larynx. Though Gowers mentions a case in which this event proved fatal, I have not come across any accident from this cause.

MENTAL DETERIORATION AND ABERRATION IN EPILEPSY.—Many epileptics, especially those who have frequent attacks, show signs of mental deterioration, which is often progressive, and which may become severe and end in chronic insanity; while others show no such mental troubles, and some of these fulfil a long life with the highest standard of capacity. There is another group in which epilepsy is engrafted upon an agenetic and, therefore, poorly developed brain which has never reached a high degree of functional activity.

There seems to be no correlation between the type of epilepsy and mental degeneration, and though the latter is widely held to be more frequent and more severe when many minor attacks occur, yet in the variety of epilepsy which will be later described as "pyknolepsy," though minor attacks occur in countless numbers, no mental degeneration ever appears. Mental degeneration seems to be the result of some peculiarity in the causal dyscrasia, which in this instance gives rise to epilepsy on the one hand, and deterioration of the higher elements of the nervous system on the other hand, as concomitant effects. Thus the epilepsy and the mental deterioration will have no factorial relation the one with the other, and this is true clinically.

The tendency to mental failure is greatest in the cases which commence in childhood, and lessens as age increases; while, again, in the epilepsy commencing in the degenerative period of later life, the incidence again increases. In its slighter form there is merely defect of memory, of attention and power of acquisition. In more severe degree there is greater imperfection of intellectual power, weakened capacity for attention, and often defective moral control. Mischievous restlessness and irritability may develop to vicious and criminal tendencies with advancing age. Every grade of

intellectual defect may be met with, to actual imbecility. Paroxysmal outbursts of mental derangement may be met with, sometimes transient and immediately following a fit, sometimes without a fit, and sometimes lasting for weeks or months. From what has been written above upon the cause of the mental disturbance in metabolic dyscrasia, these events will be easily explicable.

PERIODICITY.—While some patients may have fits at any time and at all times, yet there is a tendency in the majority for the attacks to occur at particular epochs and not at others. Epilepsy may be strictly “nocturnal” or “diurnal.” It may occur only on rising in the morning, or solely at the menstrual epoch. The fits may come in batches of several in one day, at intervals of many months, while 7-, 14- and 28-day periods are common. A knowledge of the periodicity when present is of great value in the successful treatment of epilepsy. “Rare” fits, which occur at very long intervals, are apt to present the most severe convulsion ever witnessed.

SPECIAL VARIETIES OF EPILEPSY

EPILEPSY FROM LOCAL DISEASE OF THE BRAIN.—Any lesion whatsoever of the cerebral hemispheres may produce epilepsy. But not more than 5 per cent. of all such lesions do this. The convulsions which may occur in cerebral thrombosis, encephalitis and meningitis are examples of epilepsy incident with the onset of an acute lesion. Usually the epilepsy is incident when the lesion has been present some considerable time, suggesting that the element of tissue decomposition and the liberation of toxic substances therefrom may be an essential factor. Lesions of the brain in childhood seem to be more commonly associated with epilepsy than when occurring in adult life. Agenetic states of the brain of prenatal origin (cerebral diplegias) are associated with epilepsy in 30 per cent. of the cases, and infantile hemiplegia is followed by epilepsy in about the same proportion. The lesion may be situated anywhere in the hemisphere, but when occupying the white matter near to the cortex it is more likely to cause fits than when it actually involves the cortex or than when it is deeply situated towards the basal ganglia. Increased intracranial pressure alone seems capable of causing fits, as in hydrocephalus and subarachnoid hæmorrhage, and this may be a factor in the epilepsy of intracranial tumours and meningitis. Abscess seems very rarely to produce fits.

The fits caused by local lesions are in almost every respect identical with and indistinguishable from the usual type of epileptic manifestation, from the slightest momentary minor fit, all through the local sensory and motor fits, to the severe general convulsion of instantaneous onset and immediate loss of consciousness. There are the same auras and the same sequels. It may perhaps be said with relative truth that the splanchnic auras (epigastric, cardiac, etc.) are uncommon, and that there is a greater tendency for consciousness to be lost late.

The minor attack is the least common fit occurring as the result of a local lesion; the general convulsion by far the most common; while the local fit holds an intermediate position, and its nature is often indicative of the position of the lesion. Drug treatment is more potent in arresting this variety of epilepsy.

PKNOLEPSY.—This is a form occurring in children, so called because of the great number of the fits which may occur daily. These are of the slight minor type, any sign of spasm being infrequent. It is rare for any major fit to occur. There is no mental impairment whatever, no deterioration of health, and no result is obtained by any form of treatment. The malady invariably ends in spontaneous cure, usually before or at the age of puberty.

CARDIAC EPILEPSY.—This is a convenient term for the epilepsy which occurs in Stokes-Adams's disease, and in paroxysmal tachycardia, and for the fits which may occur in congenital heart disease and in some forms of cyanosis. They cannot be the equivalents of asphyxial convulsions, for they are not met with in severe chronic cyanosis, and, on the other hand, there is usually no cyanosis at all when fits occur in Stokes-Adams's disease.

MYOCLONUS EPILEPSY.—In this group are included: (1) Epilepsy of an ordinary type in which there is much simple epileptic jactitation of the muscles between the fits; (2) cases of Unverricht's myoclonus in which epilepsy is coincident.

STATUS EPILEPTICUS.—In this condition severe convulsion succeeds severe convulsion at short intervals without any return of consciousness during these intervals. It is as if convulsion recurred so soon as the body recovered sufficiently from the exhaustion produced by the last convulsion. Meanwhile the temperature rises, and may reach a hyperpyrexia. The difficulty in feeding and watering, the severe muscular exertion and the pyrexia add the dangers of acidosis to those of exhaustion, and the patient is very apt to succumb. Acute fatty degeneration of the heart is invariably found at autopsy, presumably the result of an acute toxic process which is responsible for the convulsion. Status epilepticus must not be confused with frequently recurring fits in which there is some return to consciousness during the intervals, though it frequently develops from such a condition; for the latter are not accompanied by a rising temperature, are more readily subdued, and are not of nearly so severe a prognostic import. If the convulsions cannot be stopped by treatment, the patient usually dies from sudden collapse, or, the fits ceasing, he remains delirious for a while, with rapid heart and high temperature, and dies of cardiac failure. Status epilepticus may be met with in acute lesions of the brain, as in cerebral poliomyelitis and in chronic lesions such as general paralysis of the insane. It may occur in acute poisoning with lead, bismuth, absinthe and thujone. It may develop suddenly in any type of epilepsy whatsoever, sometimes without apparent cause, sometimes as the result of over-exertion and excitement, sometimes when medicines which have been regularly administered and which have kept the fits in check are suddenly cut off.

There is a second condition occurring in epilepsy to which the term "status epilepticus" may justly be applied. I have met with it only in epileptics who show mental deterioration. The patient, without cause or perhaps after signs of increasing mental aberration, becomes dull, ceases to take food, and lapses into coma, with terminal pyrexia, ending fatally. This is status epilepticus without convulsion, and if the convulsive form be comparable with uræmic convulsion, this non-convulsive form may reasonably be compared with uræmic coma.

Diagnosis.—The recognition of epilepsy requires a working acquaintance with the nature of its many manifestations and especially of the slight forms,

little exteriorised, which may be easily overlooked or misinterpreted. The sudden unexpected onset, without cause, the transiency, the recurrence, and the circumstances of the moment, are useful aids.

From syncopal and vaso-vagal attacks (rapid lowering of blood-pressure) epilepsy can often be distinguished by the slow onset, the gradually increasing pallor or greyness, the distancing of sound, the nausea and flatulence, the presence of an obvious cause, the length and the stillness of these attacks.

The hysterical attack is easily distinguished by the fact that only the convulsion of epilepsy can possibly be confused: the other manifestations of epilepsy are never simulated by hysteria. Hysterical convulsion has not the manner nor the march of epileptic spasm. It never begins with conjugate deviation of head and eyes to one side, there is not the orderly spread of convulsion, and there is never but a poor imitation of the sequence of tonic followed by clonic spasms. The movements in the hysterical fit are purposive, spectacular, violent, and are liable to be increased by restraint and are rapidly abolished by complete inattention. The functional fit never occurs except in the presence of an audience, for it would then be purposeless, and it never occurs during sleep. The tongue is never bitten, though other parts of the body and other people may be. The sphincters are never relaxed. Intense converging spasm of the eyes is a common feature of the functional attack, but this sign is not met with in epilepsy. When functional manifestations follow slight and rapidly transient epileptic attacks, the distinction between these and purely hysterical attacks is often difficult and sometimes impossible, except after long observation. For the initial epileptic attack may be practically unnoticeable, and the subsequent events may be typical of hysteria and are usually amenable to the same line of treatment. Often some point in the circumstances under which the attack occurs will settle the diagnosis. Any attack having occurred during sleep, or any attack in which the patient has fallen in circumstances of serious danger, as among the traffic of a London street, or any attack occurring when the patient cannot attract the attention of others, establishes the diagnosis of epilepsy. The best plan is to regard every hysterical fit as possibly epileptic, and every fit of doubtful type as probably epileptic, until time and circumstance bring definite conviction.

Migraine may sometimes closely simulate epilepsy when sudden paralysis, or sensory auras, or visual hallucinations occur without headache, and the diagnosis may be rendered more difficult by the fact that the migrainous attack may alternate with the epileptic attack, or may take its place in the same patient.

Careful search must be made in every case for all the bodily conditions with which epilepsy may be associated. Papilloedema, headache and vomiting may reveal increased intracranial pressure from some lesion of the brain; while local paralysis, sensory loss, visual or other defect may indicate a local lesion of the brain, past or present, and this may also be suggested by the nature of a local fit. The presence of rickets, infantilism, undue adiposity, etc., may indicate the presence of some definite metabolic dyscrasia or endocrine disorder. Renal function and the condition of the blood-pressure should always be examined, for even in early infancy fits may be uræmic and in the recurring epilepsy associated with small white kidney, and with cystic renal disease, the causal disease is frequently unrecognised. Where

syphilis is likely, the reactions in the blood and cerebro-spinal fluid should be examined. Lastly, any evidence of chronic intoxication by metals, alcohol, absinth, etc., should be sought for.

Prognosis.—The outlook in epilepsy is so variable that it is difficult to indicate any but the broadest principles in prognosis. Nor can a definite forecast be made in any case until the result of treatment has been watched for some time; for cases apparently favourable may prove rebellious, and those most unfavourable may turn out brilliant successes. Speaking generally, a cheerful outlook is justified in all cases except those in which there is progressive mental deterioration, and in these the outlook is hopeless in proportion to the rapidity of the mental change. Naturally, in those epilepsies which are associated with serious bodily disease, such as brain tumour, renal disease and hyperpiesia, the prognosis involves that of the causal condition.

The danger to life from the epileptic attack itself, either directly or indirectly, is not great. However severe the fit, it is extremely rare for death to occur, and when this happens it is from turning over and smothering with the wetted pillow or from choking with the aspiration of vomited material. Injury, burning and drowning may cause death, yet the number of epileptics who meet their death in this way is so infinitely small as almost to remove the danger of accident from practical perspective. In the rare status epilepticus, however, the danger to life is very great. Spontaneous cessation of the attacks occurs often enough. It is said to be invariable in pyknolepsy. The convulsive attacks of infancy, which continue for some years after all cause to which they can be attributed has passed away, often cease for ever at the age of 4 to 6 years. Again, after 20 years of age spontaneous cessation is met with, and it becomes more frequent as life advances. It is, in my experience, a much more frequent event than writers upon this subject, with the exception of Gowers, have been willing to admit.

The probability of cure, arrest or amelioration by treatment is high in all cases where no mental deterioration exists and where no insuperable bodily disease determines the epilepsy, in proportion as the only method of cure—the securing arrest of the attacks for a considerable time by drug treatment—can be adequately administered over a long period. It is greater when epilepsy is hereditary than when it is sporadic. It is greater when periodicity in the occurrence of fits allows these to be anticipated by drug administration. It is much greater when the following out of education, or the continuance of regular employment, allows of a fully occupied and satisfying life, and much less when education is stopped, pleasures and sports forbidden, and the patient condemned to social inferiority and ostracism, and to a gloomy, narrow life of inanition because he has a few fits. It is perhaps smallest when severe attacks occur daily or at short intervals.

Treatment.—*General treatment.*—The general principles for the maintenance of health if good, or for its improvement if poor, should be adopted. Whenever possible, no change whatever should be made from the régime of life of a normal person. In childhood, education, discipline and pleasures and school life should be continued upon strictly normal lines, and the adult should continue with work and occupation. No advantage has accrued from the adoption of special diets, such as the abrogation of meat, the exclusion of salt or the use of purin-free foods. Alcohol seems to be an excitant of the epileptic attack and should be forbidden.

Avoidance of excitement is usually advocated, but as this curtails the joy of existence, especially in children, it is derogatory, and it is better to fortify the patient against the attacks by medicines to be given before any exciting events. The forbidding of such pastimes as may be fraught with danger should a fit occur, such as swimming, boating, cycling and car driving, is advisable, rather because it allays anxiety for the relatives and guardians and diminishes the responsibility of the physician, than that accidents are liable to occur from such causes.

Institutional treatment.—In cases where there is low mentality, much mental degeneration or insanity, and with frequent fits, where no adequate care and occupation can be provided at home, there is every advantage in a colony, institution or asylum for epileptics. In such patients little or no good can be done by medicinal treatment, whereas regular work, discipline and interest often mitigate greatly the burden of the malady.

Surgical treatment.—The opening of the skull is a very ancient remedy for epilepsy, dating from the early Egyptians, and coming again into great prominence in the nineteenth century with the development of knowledge on cerebral localisation, and there still remains a very widespread impression that local fits and fits following upon injury to the skull are likely to be benefited by decompression. There is, however, little evidence that such procedures benefit epilepsy of any kind. When a depressed fracture of the skull exists, and the patient, his relatives and perhaps his medical attendant also, are firmly convinced that this is the cause of the epilepsy, it may be advisable to remove the defect in the bone if only to satisfy the minds of those concerned and to secure adequate medicinal treatment subsequently. Pierce Clark sums up the position adequately when he writes that "all operative measures upon the brain in epilepsy are allowable only when they are indicated by definite physical signs other than the fits." Thus, in a case of cerebral tumour producing epilepsy, operation is justifiable for the relief of the papilloedema, headache, etc., and with the hope of possible removal or of obsolescence of the growth following the decompression.

Medicinal treatment.—Further than the measures above described, the treatment of epilepsy is purely medicinal. There are two groups of drugs which have a remarkable effect in arresting or mitigating the occurrence of the attacks in epilepsy in at least 80 per cent. of the cases. They seem to have much the same effect, and may conveniently be combined or alternated in the treatment of any given case. Sometimes one group is found to suit an individual patient better than the other. No advantage seems to accrue from administering these remedies more than twice in the 24 hours, nor from using large doses. Moderate doses, such as will cause no deterioration in bodily or mental health, even if taken regularly and for years, seem to bring about the best results. The first group is that of the compounds of bromine, of which sodium bromide seems to have an advantage over the others, both as regards efficacy and toleration. The organic compounds of bromine are not so useful. Sodium bromide should not be given in larger doses than 25 grains (1.5 grammes) to an adult, nor should more than 60 grains be given in the 24 hours. It is conveniently combined with arsenic (gr. $\frac{1}{10}$) in the form of liquor arsenicalis, since this has the effect of checking the occurrence of acne. If it be advisable to conceal the fact that bromide is being administered,

Gelineau's "dragees," each of which contains 15 grains of potassium bromide, may be prescribed.

Bromism.—Even in ordinary doses, the bromides may cause some acne of the skin, especially in subjects who are prone to acne, but this is the sole derogatory effect of this remedy, which is of common occurrence. The true bromide rash, which was met with in the early days of bromide treatment when huge doses (even an ounce thrice daily) were in vogue, is highly characteristic. It is hardly ever seen in these days, but I have twice met with it from moderate doses of bromides. Mental dulling and conditions of sub-coma, which may occur from poisonous doses of the bromides, are never met with from appropriate medicinal administration. The mental deterioration due to the epilepsy in certain cases is often attributed by the laity to this cause, but this occurs, and sometimes in much greater degree, in the absence of bromides.

The second group is that of the malonyl-urea compounds, of which luminal, sodium luminal, and gardenal are examples. These are very powerful drugs, and must be used with care. Luminal has certainly the advantage over the soluble sodium luminal in being less toxic and more prolonged in its action. It is conveniently prescribed in cachets, in doses of $\frac{1}{2}$ grain to a child, and 1 grain, with a maximum dose of $1\frac{1}{2}$ grains, to an adult. In larger doses it is a powerful hypnotic, and in patients who have idiosyncrasy it may produce a troublesome kind of frenzy. It appears to be a more certain means of warding off attacks for many hours after its administration than is bromide.

Whatever remedy is chosen, whether it be the bromide or luminal or a combination of the two, it is essential if possible to anticipate the occurrence of the fit by the administration of the drug. Thus, if fits are nocturnal only, the remedy is given in a single dose at night, or if diurnal only, in a single dose in the early morning. Again, if, as often happens, the fits occur soon after waking, then the single nightly dose should be used. Or, if the fits occur or are more frequent at the menstrual epoch, they should be anticipated by increased dosage before and during that epoch. With fits that are diurnal and nocturnal, a night and morning dose should be used. As it is less important in patients who have employment when fits occur by night, and often most disastrous when they occur at work, for with the present Workmen's Compensation Act no company will insure a known epileptic, I prefer to give luminal as the morning remedy and bromide as the nightly remedy, since I consider luminal to be the greater safeguard against the occurrence of the attacks. The question at once arises, Why should two remedies be used? The answer is that these drugs are by no means identical in action, and that the nature of the cause of epilepsy certainly varies in individuals. Some patients do best on luminal alone, others on bromide alone, and others on a combination of the two, and the best course can only be determined after trial.

Many other remedies have been advocated in epilepsy; a few only have stood the test of time and are still in use, both as alternatives and adjuvants to the treatment above given. These may be placed in order of merit as zinc salts, belladonna, digitalis and allied drugs, especially *adonis vernalis*, opium and borax.

Zinc salts are sometimes very useful. In the form of the lactate (3 to

5 grains) they are easily introduced into bromide mixtures. The same may be said of belladonna, which has a marvellous effect upon a few isolated cases. It makes some cases definitely worse. Digitalis and adonis vernalis are commonly used as adjuvants, and I think sometimes with benefit. Opium and morphine, which were the standby in epilepsy in former days, are no longer used; but morphine given in careful doses is one of the most powerful means of preventing fits, and is of great use in status epilepticus. Perhaps hyoscine, advocated by Gowers, should also be mentioned in this connection. Thyroid extract is certainly of value in the epilepsy associated with cerebral agenesis (cerebral diplegia), mental and bodily backwardness and infantilism. It probably acts by rendering bodily metabolism more normal and in enhancing development.

STATUS EPILEPTICUS.—The treatment of this condition, and that of rapidly repeated fits which not infrequently merges into status epilepticus, is quite different from that of epilepsy in general, for the remedies useful in the latter condition are useless and even do harm in this urgent and dangerous state. The condition is one of acute toxæmia, exhaustion and acidosis from the violent convulsion, pyrexia, often proceeding to hyperpyrexia, and cardiac degeneration. The first thing to be done is to check the convulsion, and this is best achieved by the hypodermic injection of $\frac{1}{4}$ th of a grain of morphine. (Gowers preferred hyoscine.) Another remedy is paraldehyde, in large doses (6 drachms), and this has recently been successful at the National Hospital. It has the obvious advantage that it is stimulating and not depressant. The remedies formerly used such as bromide and chloral by the rectum are worse than useless. The next measure is to secure that the patient shall be provided with adequate stimulants in the form of food, water and even alcohol. To which end a nutritious liquid meal of high stimulating value and containing sugar to combat acidosis should be given by means of the nasal tube at regular intervals. An action of the bowel should be obtained as soon as possible, with a rapidly acting aperient administered with the food, and by warm water enemata. The pyrexia should be controlled by sponging repeatedly, and if high by continuous immersion, and this alone will sometimes have a dramatic effect in checking convulsion when pyrexia exists. When consciousness returns, feeding and stimulation must be carefully continued, with a gradual resumption of the routine treatment of epilepsy.

NARCOLEPSY.—In this remarkable and by no means rare condition, two quite different kinds of attack occur. The one is the sudden onset of apparently normal sleep, which comes usually at a moment of inattention, several times a day. The sleep lasts from a few seconds to a few minutes; it is rousable, and the patient is wide awake at once and knows that he has slept, and sometimes that he has dreamed and can describe the dream. Many of the patients have a warning in the way of a feeling of intense fatigue and, thereafter, can so far repel the onset of the attack by an effort of will as to be able to get out of harm's way; but the attack is inevitable, and it is always the more severe the longer it is resisted. The second variety of attack is called the "cataplectic" attack, and this is produced mostly from a sudden emotion, which may be of any kind, but is usually an emotion which provokes laughter. There is a sudden feeling of intense weakness in the limbs, which become flaccid. The patient drops anything that he may be holding

and crumples to the ground, but often only into the sitting position. The eyelids drop and the head falls forward with the jaw dropped, and there is sometimes twitching of the muscles of the face, tongue and neck. There is complete inability to move the limbs and generally inability to speak, but consciousness is completely retained, so that the patient is afterwards able to recount every event and repeat every word spoken during the attack.

Usually an idiopathic malady, narcolepsy has been recorded in a few instances as a sequel of encephalitis lethargica. The malady appears never to be familial, and it does not occur before the age of puberty. Once developed, it usually continues throughout life, with variable frequency of the attacks. Notwithstanding the opinion of authority that narcolepsy is uninfluenced by treatment, I have observed several cases in which the medicinal treatment customary in epilepsy had the most remarkable effect in reducing both the frequency and the severity of the attacks.

JAMES COLLIER.

MIGRAINE (PAROXYSMAL HEADACHE)

Definition.—A common malady of which the only essential characteristic is recurring intense headaches, which usually commence on waking in the morning, and which may be unilateral, frontal, occipital or general. The attacks usually date from childhood, but sometimes commence during later life. The headaches are often associated with vomiting, which has given rise to the designation "sick headaches" or "bilious attacks," with which is associated much vestibular disturbance as in sea sickness, and with peculiar disturbances of vision. Less common symptoms of the disease are peculiar slow sensory auræ, which occur in no other malady, attacks of hemiplegia or monoplegia or of aphasia, and attacks of ophthalmoplegia. Some of these phenomena may accompany the headaches, but others occur in attacks quite apart from the headaches, and may for that reason give rise to difficulty in diagnosis.

Ætiology.—The malady often commences in childhood and even in infancy. It tends to lessen after middle life, and invariably disappears in old age. Heredity is often present, and the malady will often show the same clinical peculiarities in members of the same family. The subjects of migraine are nearly always of an active, capable and intelligent type. Sometimes epilepsy is present, and the attacks may alternate with attacks of migraine.

Many theories have been advanced as to the nature of the malady. It has been held to be the result of a temporary condition of intoxication from digestive, metabolic or internal secretory disorder, which recurs periodically. There is little evidence in support of this view, for it is a common experience to meet with patients who have restricted their diets to an amazing extent to avoid the "bilious attacks," with the result that the migraine has become much aggravated. Neither has treatment directed against such errors had the slightest effect in benefiting migraine. Local spasm of the cerebral arteries has been advanced as the cause of the phenomena, on the grounds of the pallor and constriction of the vessels of the skin and retina, which occur during the attacks. This theory is adequate to explain

the varying nature of the attacks in some cases, at one time a headache, at another teichopsia and hemianopia without headache, at another, aphasia or hemiplegia or sensory aura without headache. It is, however, entirely hypothetical and breaks down utterly as an explanation of the severe and lasting ophthalmoplegia, which may accompany very severe attacks, and will hardly explain those cases in which the headache lasts for weeks, or becomes continuous. Pallor of the surface vessels, it may be pointed out, is the constant accompaniment of every severe vestibular disturbance, and many sudden changes in blood-pressure, as in sea sickness, etc. It has been held that migraine is due to a functional disorder of the cerebral cortex in the way of combined inhibition and discharge, akin to epilepsy, solely on the grounds of the nature of the visual phenomena and of the sensory auræ, and that migraine occasionally occurs in epileptics. Very undue prominence has been given to the importance of errors of refraction as causes of migraine. Certainly, such errors when existing are likely to cause vestibular upset and may therefore be exciting causes of an attack, and should in all cases of migraine be corrected. The majority of the subjects of migraine, however, have no such errors of refraction, nor has the correction of such errors ever cured migraine. Spitzner examined the brains from several cases of long standing and severe unilateral migraine, and found in each case a unilateral distension of the lateral ventricle corresponding with the side of the headache, and an anatomical condition of the choroid plexus in its relation with the foramen of Monro, such as might easily cause plugging of that foramen from conditions of turgescence of that plexus. He attributed the attacks of migraine to temporary unilateral hydrocephalus, from temporary plugging of the foramen of Monro. His specimens are in the museum of the Johns Hopkins University at Baltimore. This theory is the only one based upon pathological evidence, and it will explain migrainous ophthalmoplegia, for surely some very gross anatomical disturbance must take place within the skull to account for such sudden severe and lasting paralysis of peripheral oculo-motor nerves. For the unilateral hydrocephalus may cause pressure upon the third and sixth of one side, at the free edge of the tentorium.

The subjects of migraine are almost invariably bad sailors and bad train travellers, and mental and bodily fatigue and emotional disturbances are commonly followed by an attack. It is important to remember that tumours of the occipital lobe may be associated with attacks exactly resembling migraine. In one such case under my care, typical attacks of migraine appeared at regular intervals of about a month for 3 years. Papilloedema never developed. The patient died suddenly and a tumour was found in the upper convexity of the occipital lobe, corresponding to the field in which the visual phenomena were wont to appear. Migraine of a typical order may also occur in connection with chronic nephritis.

Symptoms.—The subjects of migraine are usually otherwise quite healthy, and are often robust and strong. No peculiarities of blood-pressure are noticeable. Premonitory signs of the attacks are present in some cases, and these may take the form of an unusual feeling of well-being and intellectual acuity, or, on the other hand, of lassitude and depression. The attack commences most commonly on waking in the morning, when on raising his head from the pillow the patient experiences a sense of vestibular

disorientation with giddiness, ocular confusion and nausea, such as is commonly felt at the commencement of sea sickness. It is at this stage of the attack, and within a few moments of its commencement, that the visual phenomena occur when these are present. Often the patient vomits at once from the vestibular disturbance, but sometimes vomiting is delayed for hours, and the vomiting may be continued as long as the giddiness persists. The visual disturbances last but a short time, but leave, as a rule, some confusion of vision and discomfort throughout the attack. The headache follows shortly upon these initial symptoms. It is cumulative, and expansile in character, and often begins constantly in a localised spot in the temple, forehead or eyeball, as a sharp boring pain which gradually spreads, and may involve the neck and arm. The pain may be unilateral, frontal, occipital or quite general. As the headache increases the face becomes pale and grey, the patient becomes much prostrated and incapable of mental or physical effort, and is unable to take food. Light, noise and movement aggravate the pain. After remaining in this condition for many hours, he falls into a heavy sleep, and awakes next morning shaken by his illness, but otherwise well. The above description covers many attacks of migraine, but many variations occur. The attacks do not always occur on waking, they may come on at any time of night or day. They may be rapidly transient, lasting but a few hours only, or they may last for days and even as long as 3 weeks, and give much anxiety in the attempts to provide nourishment and sleep for the patient. In some cases of long standing, the attacks become less severe towards middle life, and a persistent aggravating headache may develop between the attacks. When such a persistent headache is complained of alone, it is very important to inquire about preceding migraine, for the same treatment is applicable to the two conditions. One of the most characteristic features of the headache is that when once it is in full swing, no remedies will relieve it except natural sleep. Those measures so efficient in relieving other forms of headache, such as phenazone, aspirin, caffeine, morphine and alcohol, leave migraine relatively untouched.

Visual phenomena.—Considering how very common migraine is, it must be clearly understood that any visual phenomena except slight confusion of vision accompanying the attacks, are rare. These may take the form of general mistiness of vision, floating spots, scotomata, bright stars and colours, hemianopia, double hemianopia with complete blindness, or psychic hallucinations of vision. In connection with scotoma and with hemianopia, the phenomenon of teichopsia may occur as follows: Upon the dark background of the scotoma or hemianopic field, a ball of light appears, which grows larger and becomes dark in the centre. This ring of light breaks at one spot, opens out and takes the form of a series of entering and retreating angles (castellation figure) which become gloriously coloured (fortification spectrum) and which later become fragmented and fade. These visual events usually occur at the very beginning of the attack, before the headache develops, and they are rapidly evanescent, but they may occur as isolated phenomena, when no headache occurs.

Aphasic attacks may take the form of confusion of speech, word-blindness, or even of loss of speech-acceptance and exteriorisation. They accompany the headaches and occur at the commencement of the attacks. They are not of common occurrence.

Hemiplegic and monoplegic attacks usually occur quite apart from the attacks of headache. They too occur on waking, and consist of a transient uselessness and weakness of limbs, which lasts a few hours only. They are characterised by their occurrence in young subjects who suffer from pronounced migraine; they are rapidly transient and are not accompanied by organic signs, and almost invariably other members of the family are migrainous, and suffer with similar attacks of paralysis. In Michell Clarke's cases, 11 members of one family in three generations were so affected.

Sensory auræ.—These are rare events, but they are pathognomonic of migraine, and usually occur quite apart from the headaches. The aura commences upon the periphery of a limb and is likened to that which would be produced by a multitude of cold-footed insects creeping on the skin. It travels very slowly towards the proximity, taking half an hour or more to reach from the fingers to the head, and is very alarming to the patient. It disappears rapidly without further event. It is the only aura with an exceedingly slow spread.

Ophthalmoplegia.—This is a very rare but most important event. It occurs only at the height of the headache, in severe attacks. Indeed, the patients usually say that the headache, during which the ophthalmoplegia occurred, was the very worst they had ever experienced. It is a paralysis of the oculomotor nerve trunks, most commonly of the sixth nerve alone, but sometimes of the third or fourth nerves, or of a combination of these three. It is generally unilateral, but may occur simultaneously on both sides. Severe diplopia results. It passes off in from a few days to a few weeks. When once it has occurred, it is apt to recur with subsequent attacks. In one of my patients, paralysis of the sixth nerve persisted for 18 months, gradually lessening between the attacks, and becoming complete with each fresh attack of headache. It disappeared completely, with the cessation of the headaches, when adequate treatment was adopted.

Facial paralysis.—Peripheral palsy of Bell's type has been described by Rossolino as occurring in the height of a migrainous attack, and I have recently observed a very striking case in which a similar event occurred.

Diagnosis.—This presents little difficulty, if it be borne in mind that long installed recurring headaches on waking in the morning are surely migraine. The condition of the urine should exclude those renal cases with migraine-like headaches. Each case should be carefully examined for signs of organic nervous disease, and especially for persistent hemianopia and papilledema, which would indicate an organic lesion of the occipital lobe.

Treatment.—There are but few cases of migraine that cannot be materially benefited by treatment. Some are completely cured, while in others the attacks become milder and occur at much longer intervals. Careful attention should be paid to improvement of nutrition and general health, should these be defective. The avoidance of undue fatigue, and of worrying emotions, and of any factors which are known to produce the attacks, is important. Errors of refraction should be adjusted if they are important. Medicinal treatment is by far the most useful agent. A mixture containing \mathfrak{m} i of liq. trinitrinæ, \mathfrak{m} v of liq. strychninæ, \mathfrak{m} x of tinct. gelsemii, and 10 grs. of sodium bromide, made acid to preserve the stability of the nitro-glycerine, and administered thrice daily for many weeks or months, was advocated by Gowers; and truly there are few cases of migraine which do not derive great

benefit or complete cure from this treatment. Luminal, in doses of 1 grain given every night, is most valuable, and may be used in addition to the foregoing prescription. The individual attacks are difficult to relieve. Sometimes a full dose of antipyrine, antifebrin, phenacetin or aspirin given at the very commencement of the attack will ward it off, but these are useless when the headache has fully developed. Sometimes a full dose of alcohol has the same effect. It remains to keep the patient as comfortable and quiet as possible till sleep occurs. Where the attacks last over the 24 hours, and especially when they last for days, the only remedies are to induce sleep and to keep the patient nourished, the latter object being difficult to attain in long-lasting attacks. To this end hypnotics, such as veronal or adalin, may be used, and in severe cases chloroform inhalations and morphine are of value, the latter especially if there be long-lasting vomiting, for it provides rest and enables the patient to retain nourishment.

JAMES COLLIER.

CHOREA

Synonyms.—St. Vitus' Dance ; Sydenham's Chorea ; Rheumatic Chorea.

Definition.—Chorea is a spasmodic affection of the nervous system caused by rheumatic infection, and characterised by the occurrence of spontaneous involuntary movements, irregular both in time and in place of occurrence and in nature ; by inco-ordination of voluntary movements ; by muscular weakness, and by a variable degree of psychic disturbance.

Ætiology.—Chorea is rare among negroes, Indians and coloured races, whilst it is especially common in Jewish races. It is much more common among the poorer classes than among the well-to-do. Its incidence is upon nervous highly-strung subjects rather than upon the phlegmatic, and this is probably to be explained by the fact that the rheumatic subject is likely to be nervous and highly strung. Chorea is practically unknown during the first three years of life, and is very rare before the fifth year has passed. Common between the ages of 5 to 10 years, it reaches its maximum incidence between 10 and 15 years. After the age of 20 it is rare, except in connection with pregnancy ; but a few cases have been reported up to the age of 60 years which have certainly been examples of rheumatic chorea. Females are affected twice as frequently as are males. Heredity concerns the incidence of chorea in two ways : firstly, as regards the inheritance of the rheumatic tendency, which is the most important cause of chorea ; and secondly, in respect of the inheritance of the neuropathic tendency, for it is when these two are coincident that chorea is most prone to occur. A history of chorea among antecedent relations is not uncommon ; that of other rheumatic ailments is very frequent, whilst a history of neuropathic maladies such as epilepsy, hysteria and insanity is met with sufficiently often to be noteworthy. As early as 1802 rheumatism was regarded as the cause of chorea, but conclusive evidence of the connection of these maladies was first published in 1850 by G. See. In 1867, H. Roger put forward the opinion that rheumatism, cardiopathy and chorea were manifestations of one and the same disease, and all subsequent investigations have upheld this theory. The family history of a choreic patient generally brings to light the occurrence

of acute rheumatism, of cardiac disease and of other rheumatic manifestations among other members of the family. Often the patient has suffered with rheumatic erythema, purpura, rheumatic nodules, recurrent sore throat and growing pains before the appearance of the chorea; less often an attack of acute rheumatism or cardiac disease has occurred. Signs of rheumatism are very often present during the attack of chorea. Indeed, slight dilatation of the heart, with a reduplication of the second sound, may be said to be almost constant. Endocarditis and pericarditis are of common occurrence, and cutaneous rheumatic manifestations are sometimes seen, but acute articular rheumatism during an attack of chorea is unusual. A large percentage of those patients who have never shown any sign of the rheumatic state before or during the attack of chorea subsequently suffer with rheumatic symptoms. The British Medical Association Collective Investigation Committee found that rheumatism preceded the chorea in 26 per cent. of the cases, and that in 46 per cent. of the remainder rheumatic signs accompanied the chorea, or appeared subsequently. Among 115 children suffering with chorea, Dr. Batten found that rheumatic signs had occurred in 32 per cent. Three years later, he followed up those cases that had not suffered from rheumatism previously to the chorea, and among those, notwithstanding that he was unable to trace some of them, 11·3 per cent. of the total number had developed rheumatism in the 3 years following the chorea. Three years later, he found that a further 9·7 per cent. of the total had developed rheumatism. If to the total of choreic patients who present rheumatic signs at some time or other, one adds those with no personal history of rheumatism, but with a family history of rheumatism, it will be found that there are but few cases of chorea in which a personal or family history of rheumatism is absent. Pathological investigations tend also to prove that chorea is a manifestation of rheumatism. Drs. Poynton and Paine have isolated the same organism—the *Diplococcus rheumaticus*—from cases of rheumatism and from cases of chorea, and they have shown that intravenous injection of a pure culture of this organism into rabbits has produced all the characteristic lesions of rheumatism, and it has produced, in addition, the symptoms of chorea. These experiments have been repeated and confirmed by Beaton and Ainley Walker, and also by Beattie. The former observers also found that this diplococcus was present in the cerebral cortex and in the cerebro-spinal fluid in cases of chorea.

Psychical disturbances.—The association of St. Vitus' dance with fright is so impressed upon the popular mind, that any event of this nature occurring shortly before the chorea is placed in unduly important relation to the disease. In such cases, careful investigation will often discover that slight choreic movements were present before the shock occurred, and became more noticeable afterwards. Any emotional disturbance, such as fright, anxiety, depression or overpressure in school, may sometimes act as immediate determining factors, but much more often these events simply aggravate symptoms which are already present in slight degree.

Pregnancy.—The relationship of pregnancy to chorea is very definite. It is generally met with in first pregnancies, and before the age of 25 years, and in most cases the pregnancy appears to be the only obvious cause for the chorea. Drs. Poynton and Holmes, however, have gone far to prove that the chorea of pregnancy is of rheumatic origin, for they have isolated

the *D. rheumaticus* from patients suffering from this disease. The onset of the chorea is usually between the first and third months of pregnancy. It is liable to recur with subsequent pregnancies.

Pathology.—The site of the morbid process which results in chorea is in the higher part of the nervous system. This is proved by the nature of the movements, for the physiological expression of emotion is often by movements which closely resemble chorea, and the shy and nervous child in the presence of a stranger will show movements almost choreic. Further, the emotional instability and depression of the choreic patient and the association of the malady with mania in some cases, suggest that the cerebrum is the seat of the malady. The paresis and the not infrequent hemiplegic distribution of the symptoms, the major affection of the upper extremity, and the fact that the choreic movements invade the body with the same march as does the paralysis in a developing hemiplegia, confirm this view. Much light is thrown upon the question of the seat of the disease by those cases of gross organic disease of the brain in which choreic movements occur, for they prove, in the first place, that choreic movements are never met with where severe paralysis has resulted from lesion of the pyramidal system—that is to say, a relatively intact pyramidal system is necessary for the appearance of choreic movements; and in the second place, that lesions both in the post-central convolution and in the region of the deep part of the optic thalamus and red nucleus, where the superior peduncle of the cerebellum has its ending, may give rise to movements of a choreic nature. The reasonable explanation is that a lesion of either of these regions may involve the same set of nerve elements at different places in their course. Bonhoeffer is of opinion that the manifestations of chorea are due to alteration of the nerve impulses which pass from the cerebellum to the motor cortex by way of the red nucleus and subthalamic region, and the observations of von Halben and Infeld support this view, which is now widely accepted, and has been rendered almost proven by the experiments of Economo and Karplus, who have produced choreic movements in cats by injuring the region of the red nucleus. Assuming, then, that chorea is the result of a functional disturbance of the nerve elements in the region of the red nucleus, brought about by rheumatic infection, the question arises as to whether this functional disturbance is brought about by the local action of micro-organisms in this region, or whether the disorder is the expression of a general toxic state, with an especial selective capacity for the nerve elements in the region of the red nucleus. There are facts in support of either of these alternatives. That the *D. Rheumaticus* has been found massed round the smaller cerebral blood vessels, and that chorea may be local and confined to one-half of the body, support the former view; whereas the obvious general toxic state present in severe cases of chorea, and the widely spread affection of the nervous system shown by the psychic condition, support the latter view. Probably the truth lies in a combination of the two theories.

Chorea, therefore, is the expression of disordered action of the nerve cells of a particular region of the nervous system, and this disordered action results from an inherent condition of functional instability of the nerve elements, and from the deleterious effects upon these nerve elements of a specific micro-organism, the *D. rheumaticus*, which either acts locally or generally by producing a toxic blood state. The morbid anatomy of the

nervous system in cases of chorea presents no characteristic feature other than the presence of the specific organism in the vicinity of the smaller blood vessels. Alteration of the cells of the red nucleus and of the cerebral cortex in the way of swelling, distortion and tigrolysis have been described, but there is nothing characteristic about these changes. Vascular lesions—embolism and hæmorrhage—are sometimes seen when endocarditis is a complication.

Symptoms.—The onset is usually gradual, but it is sometimes abrupt, when emotional disturbance has been the determining cause. The appearance of choreic movements is often preceded by alterations in the mental and physical condition of the child. She becomes nervous and more impressionable than before; she is irritable, and often laughs and cries without apparent cause. She is increasingly unable to apply her attention, and she cannot do her lessons. She becomes clumsy in her movements—overturns her glass at table, and lets fall objects which she is holding. The inevitable reprimands, which she suffers for these faults, have an immediate effect in augmenting her clumsiness. Anæmia, apathy and languor and irregularity of appetite are commonly present. At this time, careful observation will discover slight involuntary movements of the face and fingers which are often unilateral in distribution. From day to day the movements become more marked and spread to the limbs and trunk. The face is constantly grimacing, and the hands and arms scarcely cease from turning about, and affection of the legs makes the walking irregular and clumsy. The child can no longer keep still, the respiration movements become irregular and spasmodic, and the chorea is fully developed. The characteristic symptoms of a well-marked case of chorea are—(1) involuntary movements; (2) weakness of voluntary movements; (3) ataxy, or loss of precision of voluntary movement; (4) emotional instability and other psychic disturbances.

1. THE INVOLUNTARY MOVEMENTS are always irregular as regards time and as regards the nature of the movement. Similar movements are never repeated successively in the same part, and each differs from the one which preceded it, and from its successor. Each movement begins rapidly, and ends suddenly, and one frequently sees the involuntary movement complicated by the addition of a voluntary movement to cover the fault. The majority of the movements are complicated, involving several muscles and often more than one joint. They resemble volitional movements more closely than do the other involuntary movements met with in nervous disorders, and have been called “quasi-purposive.” In the face, the movements are never confined to one side, even in hemichorea. The more simple movements take the form of asymmetrical twitches in the lips, and about the angles of the mouth and orbits. In more severe cases, the strangest grimaces may occur. At one moment the angles of the mouth are drawn downwards, then outwards, then the lips are pursed. The forehead is thrown into wrinkles, the eyebrows are brought together, then released, and the eyelids blink. Suddenly the face becomes still in a vacant, forlorn expression, to break into a quick, transient smile or ugly grimace a moment later. The tongue is thrust into one cheek, then projected just in time to escape the sudden snap of the open mouth. When asked to show the tongue, the child puts it out rapidly and holds it there by closing the teeth upon it. Smacking of the

tongue and palate may often be heard at a distance. Lateral movement of the jaw is common. According to the severity of the case, speech may be difficult, the words being articulated slowly in slurred monosyllables; or speech may be impossible, since no effective sequence of voluntary movements can be produced in lips, tongue and jaw, and since both palate and pharynx are involved in the involuntary movements. For the same reason, swallowing may be difficult or impossible in severe cases, and may necessitate nasal feeding. That the ocular muscles participate in the involuntary movements is shown by the fact that the eyes remain parallel and turn concomitantly when spontaneous movements of the head occur.

In the upper extremities the movements appear first in the hand. The thumb is more restless than the fingers, which are spread and pressed together, flexed and extended, alternately; the wrists twist about irregularly, the forearms are constantly agitated with movements of pronation and supination, flexion and extension; while all possible movements of the shoulder occur. When the upper extremities are outstretched, the hands assume the position of flexion at the wrist and over-extension at all the finger joints in so many of the cases as to make this a characteristic feature of chorea. The lower extremities are less severely affected than is the rest of the body, and here the movements are best seen when the child is lying down. The gait tends to be clumsy and insecure, the legs being thrown now too far out, now across one another, and in severe cases walking becomes impossible. Alteration of the rhythm of the respiratory movements is conspicuous and is highly characteristic of chorea. The breath is often taken rapidly and held for some time, then let go with a loud sigh. The trunk is always involved, and movements of a writhing nature are characteristic, and in severe cases these may be so violent as to throw the patient out of bed.

The face is usually the first region to present movement, and it is always affected bilaterally. The hand is the next to follow, and the left hand is said to be affected earlier and more often than the right. So far as the limbs are concerned, the movements may be confined to one side, more commonly the left side, and the condition is then called hemichorea; but the involvement of the face and trunk is always bilateral and is generally equal upon the two sides. In hemichorea, the movements are always of slight severity. Severe chorea is never confined to one side. Choreic movements cease during sleep, and, except in severe cases, can be controlled more or less by voluntary effort; the attempt to write, for example, will generally cause cessation of the movements in the right arm for the time being. They are generally increased by observation, emotion and self-consciousness, but in a few cases it will be found they are worse when the child is alone and unobserved. In severe cases, the whole of the voluntary musculature is involved and the movements are incessant. The violence of the movements of the limbs may cause the skin over the prominences to ulcerate from friction against the clothing, and the head and limbs may be badly bruised from contact with adjacent objects, and unless the patient be properly protected, wounds may occur, which are liable to infection with such grave consequences as abscess, erysipelas and pyæmia.

2. LOSS OF POWER is shown in the mild cases by incapacity for exertion and undue fatigue. More severe degrees of paresis may accompany or succeed the appearance of the movements. It may be observed that in one

limb, or upon one side of the body, the choreic movements are becoming less marked, and that the limbs are becoming progressively weaker. Soon the arm hangs loosely by the side, and the leg is dragged in walking. Though the paresis may become so severe as to make raising of the limbs against gravity impossible, yet it never becomes complete, and in almost all cases slight choreic movement persists in the paretic region. The degree of choreic paralysis bears no relation to the severity of the movements, for the former may be severe, when the latter are slight and vice versa. Choreic paresis is apt to return with successive attacks of chorea, but not always in the same region. In some cases, it constitutes the first noticeable symptom; in others, it appears late, and after the choreic movements have ceased; more commonly, both are concomitant.

Limp Chorea (chorea mollis).—This is a more severe degree of choreic paralysis affecting the whole musculature. It may be preceded by the usual symptoms of chorea. More often the paralysis is the first noticeable symptom, and this develops rapidly in from 24 to 48 hours. The paralysis is characterised by complete flaccidity of the limbs; the child lies upon its back and does not move, and if one of the limbs be raised from the bed and then released, it falls limp and lifeless. The head is no longer held in a natural position, but falls round on to the ear. Careful investigation, however, rarely fails to reveal some slight choreic movements, either in the face or in the fingers. Paretic chorea and chorea mollis run a benign course, and recovery is said to be almost invariable.

3. **INCO-ORDINATION OF VOLUNTARY MOVEMENT** may be the first symptom of chorea to draw attention, and it may precede the appearance of the choreic movements. It may be very obvious when the movements are slight, and it is most noticeable in those of the hand and forearm, which lack precision, and in those of articulation, deglutition and respiration. The motor centres do not obey the dictates of the will, so that when the patient tries to relax certain muscles for the completion of an act, there is delay, which interferes greatly with the efficacy of the act. This interruption in the sequential flow of movements which make up an act, is responsible for the sudden dropping of objects which are being carried, and for overshooting the mark in the attempt to lay hold of an object.

4. **PSYCHICAL DISTURBANCES** are common, some degree of emotional instability, failure of attention and depression being present in most cases, and, generally, in proportion to the severity of the affection. The patient's behaviour may change; she may laugh or weep without reason. She may become capricious, irritable and obstinate. The attention and memory are usually impaired, and less interest is taken in the surroundings, and this condition may progress until marked hebétude exists. Severe mental disorders sometimes complicate chorea. Delirium may occur in acute and grave cases. It is usually violent and loquacious, and resembles other forms of toxic delirium, and it is of serious prognostic import. Hallucinations of vision of terrifying character may occur. Mania is quite exceptional in children, but it is not an uncommon complication in adolescents and adults. The form of the aberration may be acute mania, melancholia, moral perversion or delusional insanity. The psychical disorders, slight or severe, usually disappear with the chorea, and in all cases the prognosis as regards permanent mental recovery is good.

OCULAR PHENOMENA.—The pupils are frequently dilated and may be unequal and excentric, and hippus may be present. Transitory squints from irregular spasm of the eye muscles may occur, and may make reading impossible. In a few cases optic neuritis has occurred and is to be attributed to the rheumatic state.

Sensibility is not usually impaired, though occasionally sensory loss of an hysterical type occurs. The sphincters are not affected. The skin reflexes are normal. The deep reflexes are also normal in a large proportion of cases, but often the knee-jerk shows an alteration which is peculiar to chorea. On tapping the patellar tendon, the resulting contraction of the quadriceps is unduly sustained, and the leg remains in a position of extension at the top of its excursion for several tenths of a second. In severe cases, the deep reflexes may be diminished and rarely may be absent for months. This loss of the deep reflexes in chorea has often been referred to the administration of arsenic, but it undoubtedly occurs in cases where arsenic has not been used, and in two cases the writer has observed a unilateral loss of knee-jerk which persisted for many months.

RHEUMATIC MANIFESTATIONS.—Cardio-vascular changes are common in chorea. In nearly all the cases, careful and repeated examination of the heart will reveal slight dilatation and reduplication of the second sound, often with reduplication of the first sound, and increased rapidity of the pulse. Doubtless these are signs of a slight myocardial weakness, resulting from the rheumatic infection. Irregularity of the pulse is probably dependent upon the altered rhythm of respiration. Systolic murmurs are common, and these may be hæmic in nature, or may be the expression of cardiac dilatation, but in the majority of cases they are indicative of endocarditis. The researches of Sturges, Gowers and Osler have shown that endocarditis is present in 90 per cent. of the fatal cases. At least one-half of all cases present cardiac murmurs, which are suggestive of the presence of endocarditis, while some cases with no cardiac murmur during life are found post mortem to have endocarditis. The mitral valve is commonly affected, lesions of the aortic valve being quite rare. Pericarditis is a frequent associate of endocarditis, only in rare instances does it occur alone. The valvular affections which are met with in chorea may be the result of antecedent rheumatism, or they may develop in the course of the chorea; or while no signs of endocarditis are present during the attack, the patient may shortly afterwards present the signs of organic valvular disease. Cutaneous affections which occur in rheumatism are met with also in chorea, namely, erythema, purpura and subcutaneous nodules. Acute articular rheumatism is comparatively rare, and when it occurs it is usually accompanied by a cessation of the choreic movements. When rheumatic phenomena are present and in the acute mania of chorea, pyrexia is usually present, but uncomplicated chorea is an apyrexial disease.

RECURRENCE.—One-third of the subjects of chorea have more than one attack. Females are more prone to a recurrence than males in about the same proportion as they are more liable to original attacks. The average interval between the attacks is one year. If, therefore, a patient has remained well for 2 years, it is improbable that a recurrence will take place. The greater the number of choreic attacks, the more likely is the heart to be found affected, and, therefore, cardiac complications are more often met with

in recurrences. In a recurrence of chorea the symptoms are usually less severe and their duration shorter than in the original attack.

Course and Duration.—The disease tends to a spontaneous termination after a variable time, which is usually from 6 weeks to 6 months. The duration rarely falls short of the earlier period. The average duration of cases treated in hospital has been found to be 10 weeks. Cases which last for more than 12 months are not rare, and slight cases with remissions may last several years. The course of the malady is that after a gradual development of symptoms, there is a stationary period during which symptoms are well marked, followed by a period of gradual diminution. Almost unnoticeably, the disorderly movements become less intense and the legs regain their normal motility, then the upper limbs, and lastly the face. The last of the spasmodic movements are seen as very slight abnormal movements of the fingers and of the face. Inco-ordination and paresis usually disappear before the spasm, but in a few cases marked paresis persists after the movements have disappeared. In some of the more severe cases of chorea where deglutition is difficult the patient is likely to be insufficiently fed; and this constitutes a grave danger, since in the condition of semi-starvation so induced, the chorea develops apace. Articulation and swallowing become impossible, and the movements become ceaseless, so that both rest and sleep become impossible; the patient wastes rapidly, and is in danger of death from exhaustion unless prompt measures for restoring the depleted nutrition are taken. This is the condition known as "chorea gravis."

The proportion of fatal cases occurring in chorea is less than 2 per cent. Death is most often met with in first attacks, occurring about the age of puberty, and it is very uncommon in young children and in recurrences of chorea. Death usually occurs from a condition of "chorea gravis." The complications which are responsible for fatal results are endocarditis, pericarditis, myocarditis and rarely hyperpyrexia.

Diagnosis.—The nature of the involuntary movements of chorea is so characteristic as to make diagnosis easy, and to avoid any confusion with other maladies which present conspicuous involuntary movements. In the tics and in torticollis, for example, like movements are repeated in the same positions. In myoclonus, the movements are short and shock-like, while in athetosis they are slow and rhythmic.

The organic diseases of the nervous system in which movements very like those of chorea occur, are easily distinguished upon careful examination by the presence of the organic signs characteristic of these maladies, of which Friedreich's disease and cerebral diplegia are the most important. From Huntington's chorea the distinction can only be made by the age of the patient, by the progressive mental change, and by the familial incidence of the disease, for the movements are identical with those of Sydenham's chorea.

When, however, movements are inconspicuous or absent and the clinical aspect is dominated by some other symptom, such as paresis or acute mania, the nature of the disease may not be so readily determined. In parietic chorea, a history of the existence of spontaneous movements before the development of the paralysis is often obtained, and careful examination will reveal slight movements in the face, or in the fingers, when a sustained act is attempted, such as keeping the mouth widely open, or holding the hand

with the fingers spread. The paresis of chorea is in itself highly characteristic. It is of gradual onset, and is not associated with pyrexia or other febrile symptoms. It is a flaccid paralysis, which is never absolute; the arm is affected more severely than the leg, and the hand more than the shoulder, while the face generally escapes. There is no local muscular wasting and no pain, and while signs of spasticity are absent, the deep reflexes are in most cases present. Maniacal chorea may be mistaken for other forms of acute mania, since the choreic movements are prone to disappear when the mania is at its height. Here the history of preceding involuntary movement helps, and it should be remembered that the rheumatic state is a not uncommon cause of acute mania in young subjects. In all cases of difficulty, the presence of a slightly dilated heart with reduplicated second sound, or the presence of cardiac murmurs in addition to the former, should at once bring to mind the rheumatic state and chorea as possible causes.

Prognosis.—The large majority, even of severe cases, end favourably, the mortality being less than 2 per cent. Complications apart, the chief peril is exhaustion from interference with taking food and from want of sleep, and the never-ceasing movements. Death from chorea in pregnancy results most often from abortion, whether spontaneous or artificially induced. The presence of endocarditis seems not to affect the immediate prognosis, but it affects the ultimate prognosis, in that it may lead to chronic valvular disease of the heart, terminating in failure of compensation with its usual consequences.

The prognosis with regard to the duration of the attack is uncertain, for whereas the attack very often comes to an end within 10 weeks, it may sometimes last as many months.

Treatment.—It is all-important in the treatment of chorea, from the mildest to the most severe cases, that physical and mental tranquillity should be secured. It is well to commence treatment in every case with several days' absolute rest in bed, provided that such treatment can be carried out without entailing the fretting which enforced imprisonment may produce. A bright room, an interesting companion, and varied amusements during the period of rest, are desirable, and isolation from other children is advantageous. It is, however, better to abandon enforced rest than to allow it to become irksome to the patient, and result in mental depression and emotional upsets—conditions above all things to be avoided.

When absolute rest is considered inadvisable, or after it has been carried out, the ordinary periods of rest should be prolonged. The child should be well clad in woollen garments, especially at night, since the spasmodic movements are liable to leave her uncovered. Improvement in the condition of bodily nutrition is to be aimed at in all cases. Choreic children are mostly ill-nourished and thin, and the effect of a liberal supply of good and nutritious food upon the course of the disease is striking. It should be impressed upon those who have the care of the child that the ordinary diet must be supplemented with as much milk and farinaceous food as she will take. When swallowing is difficult, it is best to resort at once to nasal feeding, which rarely causes as much discomfort as the ineffectual and exhausting endeavours to take food with the spoon. A china feeding-cup must never be used, since the spout may be broken off and swallowed; an enamelled metal cup is safe.

It has been pointed out above that chorea gravis is dependent upon a condition of relative starvation, and here nasal feeding should be employed, and the meal should consist of strong beef-tea, Benger's Food, lactose and milk; it should not measure more than three-quarters of a pint for a child of 8 years old. The addition of alcohol to the meal is of great value. Severe cases, in which the movements are violent, call for skilled attention, and a trained nurse is required night and day. Provision has to be made against injury from the violence of the movements. The patient should lie upon a water mattress, placed upon a large guarded bed, the sides of which are everywhere protected by pillows, which must be fixed. When a cot is used, it is easy to pad all the ironwork with cotton wool, over which bandages are wound. An excellent bed in cases of urgency can be made by placing the mattress upon the floor in a corner of the room, the walls being protected by the two halves of a straw mattress placed upright, and the other two sides surrounded by pillows. If the limbs are injured, they should be wrapped in cotton-wool applied with a light bandage.

When the patient is improving, measures calculated to enhance control of the limbs, such as exercises under supervision and simple drill, are very useful in hastening the disappearance of the movements. Warm and tepid baths and douches applied regularly and in such a way as to be grateful to the patient, and to produce no fright, are very useful adjuncts. The compounds of salicylic acid are of great value, and of these aspirin is the most useful. It should be given thrice daily after meals in doses of 10 grains for a child between the ages of 6 and 14 years, and 15 grains for an adult, and it should be continued until convalescence is complete. It is well borne and has no deleterious effect. A larger dose given at night is the best remedy for sleeplessness. The use of arsenic is followed by great benefit in some cases, but in many it fails to do good. It should be given in doses of not more than 5 minims thrice daily, as no increased benefit seems to accrue from larger doses. The value of antipyrine in chorea was first pointed out by Hubrecht, but of recent years it has largely been discarded in favour of aspirin. It may be given in doses of 10 grains three times a day. Chloretone has its advocates, but in the writers' experience it is depressing, and is much inferior to aspirin. It has the grave disadvantage that continued use, even for a short time, may induce a severe form of peripheral neuritis. Quinine in large doses has been much advocated by American physicians. In certain cases where restlessness is well marked, the administration of hyoscyne is sometimes very useful. It should be given in doses of $\frac{1}{160}$ th grain thrice daily. The administration is followed immediately by wide dilatation of the pupil and slight flushing, and by peaceful sleep. The bromides have little or no value as sedatives. In addition to the above remedies, tonics such as iron, glycerophosphates, hypophosphites, strychnine, cod-liver oil and malt are often valuable, especially in the convalescent stage.

HUNTINGTON'S CHOREA (HEREDITARY CHOREA OF ADULTS)

This is a somewhat rare disease, in which symptoms almost identical with those of rheumatic chorea, namely, involuntary spontaneous movements, ataxy, paresis and slow and slurring articulation, gradually appear

MYOCLONUS (PARAMYOCLONUS MULTIPLEX) 1561

in adult life, and usually about the age of 40 years, and are accompanied by progressive mental failure, with delusions and suicidal tendency. The choreic movements are never severe, but the inco-ordination may be well marked. Maniacal outbursts are not uncommon. The disease always progresses slowly to a fatal termination in from 5 to 30 years, and treatment is entirely unavailing. It is a familial disease, and the transmission is direct from parent to child; but if a generation escape the malady, it seems not to reappear subsequently. Sporadic cases, in which no heredity can be traced, do, however, occur. The sexes are equally affected. Further than the heredity no causal factors are known. The morbid anatomy consists in a slow progressive degeneration of the nerve-cells of the cerebral cortex and basal ganglia, with consecutive atrophy of the convolution, neuroglial overgrowth and meningeal thickening.

SENILE CHOREA

A malady in which typical choreic movements constitute the chief feature is met with in elderly people, and is possibly due to a progressive neuronc degeneration in that region affected in the other forms of chorea. It differs from Huntington's chorea in the late onset, the absence of heredity, and in the absence of mental changes.

ELECTRIC CHOREA (DUBINI'S DISEASE)

This disease, which has been met with only in Lombardy and Piedmont, is characterised by an acute onset, with pyrexia and severe pains in the neck and back, followed by spontaneous involuntary movements which are sudden and shock-like and often of wide range and powerful, resembling the movement which results from the stimulation of a motor nerve by a strong single induction shock, hence the name of the malady. Progressive loss of power occurs, the muscles waste and lose faradic excitability; the deep reflexes disappear. Convulsions are common and progressive mental hebetude occurs. The disease is invariably fatal within a period which varies from a few days to several months. It appears to be the result of an acute micro-organismal infection. Recent experience of lethargic encephalitis suggests that the epidemics of Dubini's disease which occurred during the nineteenth century may have been examples of the former malady.

MYOCLONUS (PARAMYOCLONUS MULTIPLEX)

The characteristic symptom of this condition is the occurrence of sudden shock-like contractions of the muscles, which may vary in intensity from simple fibrillary twitching to contraction which causes a violent movement of a limb. The movements are often symmetrical, and are especially incident in the proximal muscles of the limbs.

Ætiology.—The malady appears in children usually between the ages of 5 and 15 years, while in adults it commences between the ages of 25 and 40 years. Both sexes are liable to the affection. Many instances, in which

several children of the same parents have been affected, have been recorded, and in a few the malady has been transmitted through several generations. Nothing further is known as to the causation.

It is probable that the seat of the morbid process is in the cells of the cerebral hemispheres, since myoclonus is further associated with epilepsy and with progressive mental failure, and further because myoclonic movements are sometimes met with in atrophic sclerosis of the brain. Many observers, however, hold that myoclonus depends upon a disturbance of function of the lower motor neurons. Wagner-Jauregg having observed similar muscular contractions in animals after extirpation of the parathyroid glands, thinks that a disorder of internal secretion may be responsible, and records a case in which the malady was cured by thyroiodin.

Symptoms.—The movements of myoclonus are simple sudden movements, and may exactly resemble the movement resulting from a single faradic stimulus. Each movement commonly involves a single muscle only, and it may concern no more than a few fibres, resembling then the fibrillary twitching common in progressive muscular atrophy. Biancone has applied the name "Myokimia" to cases where the movements are all of this simple nature. In other cases, many muscles may be implicated in the shock-like spasms, which may be of so violent a nature as to throw the patient to the ground. The distribution of the contraction is never determined by that of the nerve supply, nor do the muscles contract according to their synergic association. Myoclonic movements are irregular as regards rhythm and range of successive movements. They are often strictly symmetrical upon the two sides of the body, and may then be isochronous. The upper limbs are more affected than the lower, and the proximal parts more than the distal, while the periphery, the hand and foot, often escape. Voluntary muscular effort usually checks the myoclonic movements, but in rare instances it excites or augments the spasm. Volitional movement is interfered with in proportion as the myoclonic movements have a locomotor effect. The electrical excitability of the muscles is unaltered, and there is no muscular wasting, but the mechanical excitability of the muscles is increased, and percussion of a muscle may evoke the spasms. The sphincters are unaffected. The reflexes, both superficial and deep, are normal. Sensory phenomena are, as a rule, totally absent, but in the cases described by Biancone as "Myokimia" subjective sensory disturbances occur. Speech may be seriously interfered with when the muscles of jaw, tongue, palate and larynx are implicated, and spontaneous laryngeal and pharyngeal noises may occur. The ocular muscles seem never to be the seat of the movements. Epileptiform convulsions are present in some cases, and for these the term "epileptic myoclonus" has been used.

Diagnosis.—This is not difficult since the simple shock-like movements in symmetrical muscles, without any resemblance to volitional movements and entirely destitute of rhythm, occur in this disease alone. Myoclonus is distinguishable from chorea by the nature of the movements, by the frequent exemption of the face, which is always involved in chorea, and by its association with epilepsy. Further, the rheumatic manifestations of chorea are not present in myoclonus. Movements of a shock-like nature may occur in hysteria, but the presence of hysterical stigmata, such as hemianæsthesia, crossed amblyopia, etc., will serve to distinguish this affection. The "tics"

can hardly be confused with myoclonus, for in the former the movements are like volitional movements, and the face is usually affected. The spasmodic utterances and fixed ideas of the severe forms of tic do not occur in myoclonus.

Course, Duration and Prognosis.—Myoclonus, as a rule, is a slowly progressive affection up to a certain stage, and when this is reached it may remain stationary for years, having little tendency to shorten life, death ultimately occurring from some other disease, without any period of freedom from the spasms. Rarely the disease has ended fatally within a few months of the onset, with progressive mental failure and coma.

Recovery may take place spontaneously, or as a result of treatment, but the affection is very prone to recur.

Treatment.—Of the first importance is the removal of any discoverable exciting cause, and the correction of any defective hygiene and mode of living. Secondly, every available measure should be used to improve the general bodily condition so as to bring about a more stable condition of the nervous elements, by improving their nutrition. The only drug which influences the disease is arsenic. It must be borne in mind that the malady is an intractable one in proportion to the time the symptoms have persisted, and that some cases recover spontaneously, and sometimes after treatment has been abandoned as useless.

SPASMODIC TORTICOLLIS

Definition.—A disease of the nervous system, characterised by tonic and clonic contraction of the superficial and deep muscles of the neck, causing the head to assume either a position in which it is turned to one side and upwards, or a position of marked retraction (retro-colic spasm).

Ætiology.—The disease is most frequently met with in middle-aged adults, but it may occur at any age from puberty onwards. It is twice as frequent in females as in males. The causation is most obscure. Not infrequently neuropathic heredity, such as epilepsy and insanity, exists, and the patients are often of highly-strung, nervous, irritable dispositions. Nervous shock, prolonged anxiety, and general ill-health have frequently preceded the onset of symptoms. Less often local strain, or injury and exposure to cold, have been the presumably exciting causes. In a few cases it appears to develop from an occupation neurosis; it developed, for instance, in a tailor who in drawing each stitch had the habit of making a short jerking movement of the head to one side. It occasionally occurs as a symptom of hysteria; but such cases should be carefully separated from those in which there is no hysterical manifestation, as being more susceptible to treatment and having no tendency to recur when once cured. A torticolic movement may occur as a variety of tic. In one case under our care typical torticollis was the end result of lethargic encephalitis.

Pathology.—No morbid anatomical changes have been found. On account of the involvement of several muscles, effecting special movements, in this disease (as is well instanced by the over-action of the frontalis in retro-colic spasm, for retraction of the head is always normally associated with raising of the eyebrows in the act of looking up), it is probable that

torticollis is due to disorder of those centres which direct such associated movements of the affected muscles.

Symptoms.—The onset is usually insidious, but in rare cases may be quite sudden, as in the case of a man aged 40 years, who, when walking along a London street, suddenly turned his head at the sound of an accident which shocked him severely; he was unable to turn his head back without using his hands to do so, and he subsequently developed the most severe torticollis. The initial symptom is always spasm, which may be either tonic or clonic, and frequently both forms of spasm are combined in the same case. In the tonic form, the head is retracted and the face turned to one side, usually the left, and owing to the retraction of the head the face is turned upwards. The shoulder on the side to which the head is inclined is usually raised. In severe cases all the muscles of the upper extremity, the scaleni and the face muscles, may become involved. The spasm, except in the earliest stages, always involves muscles of both sides of the neck. Where the bilateral involvement is general and equal, the rotation of the head does not occur, but it becomes strongly retracted, and the condition is then known as retro-colic spasm. Such retro-colic spasm is always accompanied by marked over-action of the frontales, the skin of the forehead being thrown into transverse wrinkles. In the clonic variety there is jerking movement of the same muscles, usually associated with some degree of tonic spasm. The eyes do not follow the movements of the head in the jerks. The muscle primarily involved is the sterno-mastoid, the action of which is to incline the head forwards and towards the shoulder of the same side, and rotate the face to the opposite side. The next muscle involved is the splenius of the opposite side, which inclines the head backwards and rotates the face towards its own side, its rotatory action thus coinciding with that of the opposite sterno-mastoid. When the splenius of both sides act together, the head is strongly retracted. Next to be affected are the upper part of the trapezii, the trachelo-mastoids and other deep neck muscles, and with further spread of the spasm, any neighbouring muscles of the shoulder and upper extremity may be affected. Sleep causes cessation of the clonic spasm, but not always of the tonic spasm when the case is severe. The spasm is always increased by fatigue and excitement. There is no wasting of the muscles involved, but on the other hand, they may be even hypertrophied if the spasm has existed for long, and their electrical excitability may be increased. The amount of pain associated with the spasm varies greatly. There may be a slight feeling of cramp only, but usually there is a great deal of aching pain, which may radiate down the arm and into the side of the head, and make life unbearable to the patient. More rarely, sharp neuralgic pains are present.

The course of the disease, which has no tendency to shorten life, is chronic, exacerbations and remissions under treatment being common, and recurrence, after temporary cure, frequent.

Diagnosis.—This is usually quite simple. Fixed positions of the head associated with spasm occur in disease of the cervical spine, especially in spinal caries, and are also associated with enlarged lymphatic glands in the neck. The local signs of these conditions, however, are characteristic.

Treatment.—Temporary relief is often obtained by the administration of chloral and bromides; keeping the patient constantly asleep for a period

of three or four weeks by the administration of chloral hydrate in 10-grain doses administered 6-hourly, the patient being meanwhile isolated from noise and disturbance, has produced permanent benefit in several cases in the hands of Bastian. Morphine always affords temporary relief, but its use is fraught with the danger of the patient acquiring the morphine habit. In one long-standing case recovery followed deep etherisation repeated on several occasions. Hyoscine may be of advantage in some severe cases, but it must be used with care. Psycho-therapeutic treatment is often very useful, and that physician who most completely gains the confidence of the patient is likely to be the most successful in improving the condition. Massage and sedative galvanism and passive and active movements with retraining in control, are all helpful measures. Suspension by the neck, so arranged as to be more impressive than punitive or dangerous, is helpful.

Surgical procedures meet with temporary, sometimes with permanent, success. Tenotomy of the affected muscles rarely gives lasting relief, and the same may be said of the division of the nerves supplying the affected muscles, for such nerves rejoin. The operation of Keen, in which there is extensive exsection of the posterior branches of the spinal nerves supplying the affected muscles and of the spinal accessory nerves, has given encouraging results. Kocher recommends exsection of the whole sterno-mastoid muscle, and Chiene advises extirpation of that cortical centre (*No. 12 of Ferrier*) which is associated with the movements of lateral rotation of the head. The great disappointment with all surgical procedures is the tendency of the spasm to spread to other regions after operation. In a severe case of torticollis, it can readily be demonstrated that in the severity of the spasms all the muscles on both sides of the whole trunk, and even those of the leg, are involved.

There is a *congenital form of torticollis* which is of a very different nature. The disease is pre-natal and analogous to congenital talipes, the sterno-mastoid alone is affected, and nearly always that of the right side. Such a muscle is frequently ruptured during birth, and this has given rise to the opinion that the birth injury and subsequent hæmatoma of the muscle was responsible for the torticollis. In many of these cases there is marked facial asymmetry, the face being smaller on the side of the affected sterno-mastoid. This association points strongly to some defect in the nerve centres of the medulla.

Treatment.—This consists in tenotomy of the contracted muscle.

THE TICS

Definition.—A group of maladies characterised by the occurrence of either—(1) sudden, rapid, twitch-like, involuntary co-ordinated movements, always of the same nature and in the same region; or of (2) sudden psychical phenomena, imperative ideas and explosive utterances; or (3) of a train of deliberate highly co-ordinated actions produced by an imperative idea. Any combination of these phenomena may occur.

The tics are both ætiologically and clinically related to spasmodic torticollis, into which some of the motor tics gradate. A torticollis movement

may occur as a tic, and it may in rare cases pass over into an established torticollis.

The tics may be conveniently divided for clinical purposes into the following groups, between which any combinations may occur :

1. The clinical picture is made up by the occurrence of sudden twitch-like co-ordinated movements, which resemble reflex or defence movements. The movement is always of the same nature and occurs in the same region, though several different tics may occur in the same patient. The usual region affected is the face, with the pharynx and larynx, the neck and upper extremity. This form occurs chiefly in children, and usually runs a favourable course—Simple Tic.

2. The spasms are more severe and complicated than in simple tic, and imperative ideas and explosive utterances are common and important symptoms. The condition is met with soon after puberty, and more commonly in males—Convulsive Tic.

3. There is no spasm or other motor manifestation, but the psychic tic is expressed by uncontrollable imperative ideas, explosive utterances, arithmomania, etc.—Psychical Tic.

4. Under conditions of mental stress and embarrassment, and in conditions of boredom, the patient performs some highly complicated and co-ordinated act which relieves his nervous tension and fascinates him—Co-ordinated Tic.

The tics are expressions of unrest and of physiological embarrassment in consciousness in a nervous system which is highly sensitive and not too stable. There is always the desire to relieve the embarrassment by the occurrence of the tic, and a feeling of relief when it has occurred, coupled often with disappointment at the failure of its suppression.

While the more simple forms of motor tic from their pattern suggest strongly that they are caused by some peripheral irritation from the conjunctiva in the case of a blinking tic, from the nose in a case of snuffling tic, and from the larynx in a case of laryngeal tic, and that constant irritation from these regions has set up a habit, yet it cannot be too strongly pointed out that no such peripheral irritation precedes the onset of tic, for the irritation and cause come from within the nervous system. Severe peripheral irritation does not cause tic, nor does the correction of errors of refraction, the removal of tonsils and adenoids and of teeth, or circumcision aid in the cure of the malady, though it is only too common to see cases in which these procedures have been inflicted upon the tiqueur one after the other, to the detriment of his tic and of his general health.

SIMPLE TIC. HABIT SPASM

This is a common disorder of late childhood, the majority of the cases occurring between the fifth and the tenth year. Either sex is prone to the disease. The onset may be preceded by deterioration of health from any cause, and sometimes fright and emotion bring on the tic. Often the malady arises in perfectly healthy children without assignable cause. The children are usually highly strung and intelligent. It is a rare event to see a dull and backward child with a tic.

Symptoms.—The recurring tic appears somewhat suddenly, and may

reach its height in a few days. The movements are of the nature of a simple act. They occur suddenly and without warning, and are executed rapidly. Usually the movement is of one kind only ; but sometimes several movements coexist. The common site of the spasm is the head, face and neck. Blinking, winking, alternate elevation and depression of the eyebrows, side to side movements of the mouth, tossing the chin in the air, sudden movements of the tongue, palate or larynx, accompanied by an unpleasant fidgeting sound, are of frequent occurrence, while any movement of the head upon the shoulder, torticollic movements, shrugging of the shoulder, and any movements of the arm may be met with. Respiratory movements are often associated with those occurring in the tongue and larynx. Tic affecting the legs is much less common. The movements cease during sleep. Generally a variable time of some length separates the individual movements, but in severe cases these may follow one another almost unceasingly. They are increased by excitement and by observation, and can usually be controlled by the will, but only for a limited time.

Diagnosis.—The movement of tic is so peculiar that it cannot be confused with any other spontaneous, involuntary movement. It is the same movement, repeated with very rapid execution, in the same place. It is short and sharp, like a twitch. In chorea the movements are slow compared with those of tic, and are irregular in nature, in time and in place.

Prognosis.—Most cases of simple tic recover, whether they are treated or not. They recover much more quickly under treatment, and two or three months suffices in most cases to see the end of them. The longer a tic lasts, the more difficult it is to cure. In the rarest cases only does a tic of this nature persist or merge into one of the more severe forms.

Treatment.—A scrutiny of the general health should be made, and any defects attended to. Matters of hygiene, diet, education, exercise and pleasure should be correct and normal. Observation and remarks upon the child's defects, and anything tending to increase self-consciousness should be avoided. The confidence of the child should be gained if possible, and any source of mental worry, or grief, or annoyance should be ascertained and comforted. Restraint and discipline should be kindly taught, and an orderly life followed in which the child is happy, and in which his time is fully and congenially employed. In severe cases only is it necessary to interdict all physical and mental exertion and excitement, and enjoin rest in bed, and these measures should only be employed for a short time. Aspirin in 10-grain doses 3 times a day is a most valuable remedy, hardly to be dispensed with in any case. Tonics are often useful.

CONVULSIVE TIC

In this malady, which was first described by Gilles de la Tourette, and which bears his name, the same movements as are met with in simple tic occur ; but these are more severe and more widely spread, and they may involve the whole body in spasm at one time. In addition, there are psychic tics, which cause irresistible impulses, among which are explosive utterances, repetition of words, sounds and gestures, and also imperative ideas.

Ætiology.—The stigmata of physical and mental degeneracy are rarely absent, neuropathic and sometimes direct heredity is often present. The malady is said to be more common in males, and is met with more often in France than in England—where it is a rare disease. The symptoms appear usually between the ages of 10 and 15 years, and commonly follow physical or mental shocks or acute illness of any kind.

Symptoms.—The spasmodic movements resemble at first those of simple tic in their nature and rapidity, and favour the same sites ; but they are not restricted to the repetition of the same movement, but successive movements may vary widely in position and extent and sometimes involve the whole musculature of the body. The great variety of facial grimaces, head jerking, grotesque attitudes and ridiculous pantomime which may occur in this affection lead commonly to the belief that the patient is shamming. The tic is not continual as in the simple form. It occurs in the form of bouts in which the same pantomime is reproduced. These are often excited by observation and emotion. They can often be controlled, but with much fatiguing effort on the part of the patient, who becomes so worn out with half successful efforts to control them that he ceases to make the attempt. Between the attacks the patient seems quite normal. The psychic phenomena are the same as in psychical tic, about to be described, and the treatment of the two conditions is identical.

PSYCHICAL TIC

In this condition there is no muscular spasm : but the sudden event takes the form of explosive utterances, imperative ideas and impulsive acts. This condition often occurs as a part of convulsive tic. The exclamatory tic consists of some sound or word or group of either, which is habitually uttered, with complete irrelevancy of time, place or sense. Sometimes the words are of an obscene nature and cause the greatest distress to the patient, who, often of innocent mind, is never safe from putting herself to shame. The utterances may be single, or may be repeated over and over in rapid succession. Echolalia, which is an uncontrollable impulse to repeat sounds heard, or to repeat words which the patient or others have just spoken, may be met with. The great characteristic of the condition is that though the patient desires above all other things to prevent their occurrence he cannot do so by any effort of will. Other symptoms that are commonly met with in this condition are imperative ideas and impulsive acts of all sorts, and in addition insanity of doubt, agoraphobia, acrophobia, mysophobia, etc., and arithmomania. In severe cases grave signs of mental deterioration slowly supervene, judgment and memory fail, will power and attention are lost, and the patient becomes incoherent and insane.

Diagnosis.—Both in the convulsive and psychical tics the diagnosis is placed beyond doubt, both by the nature of the movements and by the peculiarity of the psychic disturbance.

Prognosis.—Permanent recovery has occurred from both these conditions ; but such an event is rare. Most of the cases follow a downward course despite treatment, and many end in suicide or insanity.

Treatment.—General tonic treatment, with change of circumstance and kindly moral and physical discipline, with healthy pursuits and congenial intellectual and physical occupation are the most likely to benefit. When

fixed and imperative ideas are present the patient must be guarded, as one of unsound mind.

CO-ORDINATED TIC

In this condition complicated co-ordinated movements are habitually repeated without apparent cause or purpose—especially in conditions of mental stress. It can be best illustrated by the account of an individual case under our care: A brilliant scholar at a public school was noticed to absent himself for no apparent reason, and when sought for, on the occasions on which he could be found, was always discovered in some secluded place rapidly revolving the two index fingers round the inside of a loop of string. He explained to me that this act had always given him relief from mental stress and anxiety, and that he was ashamed of it, and did his best to overcome it, and often succeeded, but that sometimes the desire for relief from stress overcame him. He was treated, and had no return of the tic for some years. He had become head boy of the school and captain of the football team, and on the occasion of the match of the year with another great school, with much anxiety and responsibility upon his shoulders, at the moment of the commencement of the match the captain was not to be found. He was recovered from the act of revolving his index fingers round the inside of a loop of string in a secluded place, in time to perform brilliantly and win for his side.

CRAFT PALSY

Synonyms.—Occupation Palsy; Occupation Cramp.

Definition.—A peculiar malady determined by the habitual use of one set of muscles for the constant repetition of an act of short range, to the exclusion of acts of wider range and acts involving a different set of muscles. The symptoms are—(1) local pain in the muscles concerned; (2) local spasm of the muscles; (3) loss of volitional control of the range and nature of the movements; and (4) weakness of the movements. These symptoms may occur separately or together.

Ætiology.—This disease may be occasioned by any occupation which requires the constant repetition of movements of small range, and which necessitates the holding of the limb rigidly for the fine co-ordination, to the exclusion of free and wide range movements. Consequently it is almost confined to those employments involving finely co-ordinated movements of the fingers, hand and upper limb. A cramped, restricted and laborious method of using the upper limb for fine acts is more likely to bring about the condition than is a free and graceful style, and faulty methods of teaching and of learning a skilled occupation with the hands are doubtless factors in some cases. Heredity and neuropathic conditions have no causal connection with the malady, nor have local abnormalities in the form of arthritis, neuritis, or organic nervous disease. The malady is certainly of central origin, and the combination of pain, spasm and loss of control and tremor points to the region of the basal ganglia as the site of the breakdown in function which produces the disability. We have seen two cases in which, as the result of a vascular lesion involving the subthalamic region, a condition almost exactly resembling writer's cramp occurred.

A personal idiosyncrasy is more important than long years of occupation, owing probably to some inherent weakness in the nervous mechanism concerned. For this reason young people are apt to break down with the malady during their training. Two of our patients developed severe writer's cramp when learning to write in infancy, and the condition persisted throughout life, though their attainments in other directions produced brilliant careers. In the telegraph service breakdown during training is not uncommon. The highly skilled trained hand, who has had years of service, and has reached the acme of facility and perfection in his manipulation, is unlikely to break down under normal circumstances; but he is liable to develop the malady under conditions of general ill-health, or if he undertake excessive hours of work above his usual limit, and especially if he cease his work for a long period and again resume it at high pressure. This last factor was very evident after the Great War, to which many skilled telegraphists went, to be used for every other duty except telegraphy. On demobilisation many of these men resumed their work, not having touched a telegraph instrument for years, and proceeded at once, and without difficulty, to work full hours upon the most exacting of instruments, with the result of a breakdown with telegraphist's cramp within a fortnight. It must be especially borne in mind that the incidence of the disease is not in any direct relation either to the nature of the work or to the length of working hours, but that the personal factor is of high importance. The following is a list of some of the occupations in order of frequency in which this malady occurs: Telegraphists, writers with the pen, seamstresses, violinists, machinists, gold-beaters, cigar and cigarette rollers, dairy milkers, pianists and typists. While in some mild cases, and for a time in other cases, the disability may occur only when one act is being performed, yet it is usual in more severe cases for many acts to be interfered with, and in a few cases all finer actions in the affected limb may be severely affected. For example, it is the rule to find that a patient who is suffering from telegraphist's cramp is also affected with writer's cramp, and with inability to shave with the right hand and, if a woman, she will be disabled with her needle, and in severe cases there may be difficulty in using a knife and fork, doing up buttons and so forth. The very general use of the typewriting machine, with its free and multitudinous movements required for its manipulation, has made writer's cramp a very rare disease compared with years ago; but it must be borne in mind that when the malady is once installed it is likely to follow the sufferer from one occupation to another. As an example, a telegraphist developed cramp in manipulating the Baudot instrument. He was rested and transferred to lighter duties involving the use of the Morse instrument, where he after a time failed. He was then transferred to counter duties, involving the use of the pen, and became incapacitated with writer's cramp. He was then used to close envelopes, and developed cramp over that act, and ended his service as a messenger. Several of the occupations above mentioned are scheduled in an Act of Parliament as dangerous trades, owing to the liability to cramp, and the employer is bound to compensate for such disability arising in his employ. Other occupations are not so scheduled; the gold-beater, for example, has to bear the brunt of his own incapacity.

Symptoms.—It is usual to divide the symptoms into two groups—(1) the subjective, consisting of pain, discomfort and the peculiar tired, heavy feeling

in the muscles; and (2) the objective, consisting of the visible spasm, the slowness, the ineptitude in timing, the trickery in dodging the disability, the tremors and the defects in pattern of the work produced. In some cases subjective symptoms alone exist, and others pass through a subjective stage before objective symptoms develop. The subjective cases suffer greatly, and are too often looked upon as malingerers, neurotics, or are labelled with the diagnosis of neuritis. The pain varies from a discomfort such as every one experiences in the deltoid muscle if a weight be held out at arm's length for a considerable time, and which compels one to drop the arm, to a severe, heavy, boring pain. Its seat is in the muscles, and never in the joints. It occurs most often in the forearm and hand, but may frequently begin in the upper arm or shoulder muscles. In slight cases, it ceases so soon as the act is discontinued; in more severe cases it may last for hours, or even days, after strenuous work. As the disease progresses it is apt to appear sooner and sooner after work is commenced. Even in the worst cases free exercise of the arm, such as swimming, tennis playing, etc., never brings on the pain, but on the contrary, relieves it. The pain never spreads beyond the limb affected.

The objective symptoms may often exist without the subjective throughout the whole course of the disease. The first thing noticed is that the fingers stick down when they are required to be lifted, for a fraction of a second, making the movement late and throwing the timing of movement into disorder. The muscles will not obey the will at the right moment. This stiffness is referred to as the "cramp"; but it is not a painful cramp. It increases and spreads from the muscles of the hands to the rest of the arm, and is apparent to the observer as an awkward and clumsy attitude. In writer's cramp, for example, the pressing of the wrist upon the table, the raising of the elbow which is carried away from the body, and the tight clutching of the pen are characteristic. To evade the spasm the sufferer employs another set of muscles, often very cleverly. The penman alters his grip of the pen even in grotesque ways. The telegraphist at the Morse key substitutes his left hand, or keys with the outer side of his hand. These workers have innumerable tricks for dodging the spasm. In going round the telegraph galleries at the General Post Office it is perfectly easy to pick out all the cramp subjects, from the appearance of the limb during the performance of the work. The spasm may reach such intensity as in a writer to perforate the paper and break the pen. The result of the disability upon the pattern of the work produced is the lack of decision in execution that characterises all fine work; the timing becomes slower, the regularity becomes broken, the excursions become less free and, therefore, the work becomes smaller, while suddenly occurring spasm and tremors are apt to produce conspicuous irregularities. Tremor of a very fine order is present in some of the cases, but is not constant. It is a very curious fact that slight lowering of excitability to faradism is present in most of the cases. The varieties of this malady need but short description, for the symptoms and signs are the same in all.

WRITER'S CRAMP

The subjective signs are usually well marked. The objective signs appear first towards the end of the day's work, when writing tends to lose its precision

and regularity, and to become smaller, and the writer finds that he has to grip his pen more firmly, and to take more support from his desk to write steadily. The difficulty appears earlier in the day as time goes on and spasm increases, with a gradual deterioration in the quality and size of the writing, there being especial difficulty in keeping the writing in line. The writing becomes angular from sudden spasm, and catching of the pen-point in the paper causes much ink spluttering. In severe cases even taking the pen into the hand may bring on the spasm.

TELEGRAPHIST'S CRAMP

There are four instruments commonly used for sending. The Morse instrument is a hard contact key provided with a spring and knob, and the manipulation is performed by making the contact against the spring pressure with the knob held loosely in the palm of the hand. The movements involved are flexion and extension of the wrist only. The arm is supported from the shoulder only. This is a bad cramp-producing instrument, but it has the advantage that it can be manipulated with either hand. If telegraphists are taught to be ambidextrous from the first the incidence of cramp falls to a very low level.

The Baudot instrument consists of a piano board with five keys, which are manipulated by three fingers of one hand and two fingers of the other, and with the permutations and combinations of these five keys all the signals are made. The movements have to be synchronised to the beats of the commutator. The forearms and wrists rest upon the table. This is the worst cramp-producing instrument that ingenuity could devise, for the movement is of the fingers only, and it is utterly restricted both in space and in time. The Hughes instrument is a piano keyboard with many more keys, and its use is not often productive of cramp. The Gell instrument is a typewriter keyboard, and the movements are free. It is the best instrument in so far as it is not a producer of cramp. Two points of interest stand out, especially in connection with cramp in telegraphy. The one is that, notwithstanding the discomfort, spasm and obvious disability, the subject is rarely reported for faulty sending, so great is his aptitude for dodging his disability. The second point is that so many subjects will work for years, and often to the end of their service, with very obvious cramp, which never proceeds to incapacity.

GOLD-BEATER'S CRAMP

This condition is here described not because it is common, for the workers at this trade are very few, but because it emphasises the lack of precision in movement, which is so important a feature in occupation palsies. The work consists of tapping with a heavy round-faced hammer upon a pile of tiny gold discs separated by layers of gold-beater's skin. By repeated tapping the gold discs are pressed out into as many gold leaves. The contact with the hammer must be made with a precision greater than one-hundredth of an inch. With the onset of the cramp this precision fails, and the leaves are cut at the edges of the disk and the work is spoiled.

Diagnosis.—The peculiar and characteristic nature of the symptoms of craft palsy leaves no reason for any confusion in diagnosis. The production

of the symptoms only during work of a very special nature, and their cessation the moment it is finished, the fatigue phenomena and the absence of all signs of organic disease make up a sufficiently definite picture. It cannot be too forcibly pointed out that local conditions in a limb, such as arthritis, neuritis, etc., have no causal connection with craft palsy. They may coexist, but they cannot confuse even then the correct diagnosis, for they do not produce symptoms like those of craft palsy.

Course and Prognosis.—In a young subject, who shows signs of the malady during training or soon thereafter, the outlook is hopeless with regard to continuance of the occupation, and the progress is from bad to worse. In older subjects the course varies greatly. Some cases recover completely and permanently, even though they continue with the occupation. In others—and this class is much larger than is usually supposed—the condition of cramp becomes stationary, and persists though not in disabling fashion. In a third and numerous group it progresses to incapacity, and tends to reappear with every change of occupation. In a few cases the patients become incapacitated for all the finer movements of both hands. The prognosis is usually serious; but a correct forecast can only be made from the history and progress of each individual case.

Treatment.—The responsibility and costliness which the Compensations Act entails upon employers are slowly enough but surely leading to the abandonment of those instruments, the manipulation of which may produce cramp. Good teaching of unconstrained methods of manipulation and encouragement of ambidexterity in all the occupations concerned are important prophylactic measures. Long hours and the speeding up of work should be avoided. After long absence from work, the work should be gradually resumed and not recommenced at full pressure. When the malady appears, rest and change of work afterwards are absolutely essential. Long-continued rest, be it remembered, cuts both ways for, as has been pointed out above, resumption after long rest is actually a cause of cramp, for long unemployment decreases the stability and the aptitude of the mechanism. General hygienic and tonic treatment are important. It is doubtful whether local treatment, in the way of massage, electricity, etc., can do any good, except to satisfy the patient. Sporting exercise of any and every kind is most useful. The Post Office authorities adopt the very admirable plan of re-training cramp subjects by daily practice with the instruments for a few minutes, the time of practice being gradually lengthened as capacity increases.

CRAFT ATROPHIES

Under this title are described a medley of conditions in which local atrophy of muscles, pain, numbness and sensory loss occur in connection with regions which are habitually over-exerted. It has been met with in platers, filers, file-makers, locksmiths, rowers, glassworkers, etc. The condition seems to be really one of local traumatic fibrositis, involving the nerves, and produced in some cases by the continued pressure of the tools.

Many of the cases recover with rest and treatment appropriate for a local interstitial neuritis.

JAMES COLLIER.
W. J. ADIE.

HYSTERIA

Definition.—The term “hysteria,” first introduced by Aretæus, who linked hysterical manifestations with disorders of uterine function, is used for a series of mental and bodily disorders which have peculiar and striking characteristics, and it must never be used as a mere limbo in which to place ill-understood maladies, or those that evade diagnosis, and which do not present its characteristic features. This is the more important since hysteria may occur in the presence of organic disease, and superficially it may simulate organic disease closely.

It has its origin invariably in psychical upset of a negative emotional tone, either determined externally, as by terror, grief and injury, or having some cause from within, in mental unrest, conflicting emotions, inability to cope with the environment, and failure to deal with the problems of life in general. The individual with nervous instability, hereditary or personal, certainly forms easy ground for the development of hysteria, but it seems unlikely from the experience of the Great War that any of us are immune to the causes of hysteria, provided they are applied forcibly enough and for a long enough period.

There is always a complete absence of any of the signs of such organic disease as could produce the symptoms. The nature of the latter is often highly peculiar and sometimes pathognomonic, and often “contradictory signs” are present. Hysterical attacks are characterised by never occurring during sleep, or unless an audience is present or within call, by an immediate emotional cause, by the fact that the patient works himself up into the attack, by the highly spectacular display, with expression of emotion, and absence of tongue-biting and incontinence, and by the effect of complete indifference on the part of the audience in causing the attack to cease. In hysterical paralysis, when this is incomplete, the attempt to perform an act to order is associated with the contraction of the antagonists before that of the prime movers, as if to prevent the act being performed, and the resulting movement has a peculiar broken and tremulous quality. The strenuous efforts to perform the act commanded produce visible effort and contortion of any or every part of the body, to the exclusion of the muscles concerned with the act required. The patient does his worst under favourable circumstances to obey the word of command, often with much emotional and noisy respiratory disturbance. In organic paralysis, on the other hand, it is usual for the patient to do his best under difficult circumstances, and the picture is in high contrast to that seen in hysteria. When functional contracture is present, there is the distinguishing feature that any attempt to straighten out the contracture passively is productive of such intense emotional disturbance as is hardly seen in painful organic conditions.

The mental condition of hysteria is that of functional lowering, dullness and lack of attention to the environment, and in severe cases this may amount almost to amentia. Lastly, hysteria is characterised by the possibility in every case of miraculous cure—even instantaneous—sometimes by accident, sometimes by events which raise the emotional tone, usually by some kindly, dominant and insistent personality who impresses the patient that he can cure him, demonstrates that the paralysed organ can be used naturally, and that the senseless limb can feel, and convinces him of these facts.

Pathology.—Neuropathic heredity is frequently found. It is said to be more prevalent among the Latin races and Hebrews than among the Saxon races. The condition is more common in women, but during the Great War it was infinitely more common in men, from the long-continued exposure to terror, stress and injury. As caused by accident, it is always more frequent in men. The incidence is in young adult life, from the age of puberty until the end of the fourth decade; but it occurs sometimes in childhood and also in the later years of life.

Predisposing causes often exist in the way of inadequate education and training in the development of a well-ordered, well-disciplined and well-employed mode of living. Feeble health, privation, long hours, overwork and debilitating influences, and the absence of the natural feelings of well-being which these entail, are often factors. By far the most important exciting causes are mental emotion, shocks, and physical injuries, while long-continued anxiety and tension, disappointments, money losses, frights and bereavements, and railway and carriage accidents are frequently the immediate precursors. The conditions of modern warfare, with constant aerial and high explosive bombardments and burials, are potent factors. Even the Workmen's Compensation Act, if not in causal relation, seems to be a factor in the maintenance of the condition when once developed. The emotional instability which occurs in some women at the time of the menopause is a factor in the production of some of the cases occurring at that age.

Charcot considered that hysteria was an abnormal condition of mentality, in which morbid states, such as paralysis, anæsthesia and fits, are ideationally induced, and he laid stress on the "fixed idea" in the genesis of the symptoms. He first demonstrated the possibility of producing hysterical phenomena by suggestion and also causing them to disappear by suggestion. He laid it down that some of the symptoms which he called the "fixed stigmata" usually develop without the patient's knowledge, such as the varieties of sensory loss, both special and general. Other symptoms which he called "transitory stigmata" developed under the influence of the patient's knowledge and emotion, and in this group he included fits, palsies, contractures and aphonia. The importance of the fixed idea in hysteria is great, and to remove such fixed idea is to cure the patient. The separation of the symptoms into the groups of fixed and transient stigmata is much too arbitrary, for symptoms of the second group will often be found to appear without the patient's knowledge.

Janet considers that hysteria is a functional disturbance of the cerebral cortex, which amounts to a severance or dissociation of some mental processes from the main personal consciousness, and this dissociation is the basis of both the temporary and the persistent signs of the malady. In the hysterical fit, the patient passes through a phase of movements and actions of which there is little or no subsequent remembrance; and in hysterical paralysis there is suppression which amounts to loss of consciousness of the existence of the paralysed limb or organ.

Babinski holds that the phenomena of hysteria are due to self-suggestion in an unstable mentality, and he would limit the phenomena, which he collectively calls "pithiatism," to those which can be produced by suggestion and removed by persuasion. When so-called hysterical phenomena cannot be so removed and reproduced, they are either matters of stimulation and

deceit, or they are real phenomena, brought about for purposes of deception, such as erythematata, ecchymoses, ulcerations, blisters, œdema, etc.

Freud, whose recent work upon this subject has attracted great attention, bases his theories upon the doctrine of psychogenesis; no mental event is undetermined and due to chance. He accepts Janet's ideas of dissociation and psychical automatism, and holds to Binswanger's insistence upon the ætiological importance of affect. He considers that mental phenomena are capable of a psychological explanation without reference to physiological processes occurring in the brain, and that it is possible to explain mental processes by scientific laws involving psychological terms only. He assumes the existence of psychical process of which the subject himself is entirely unaware. This is the conception of the "unconscious mind." The origin of hysterical symptoms is to be sought in ideational complexes, with marked feeling tone, which come about as the result of psychical and physical trauma. A "complex" is a system of ideas having a definite emotional tone and conative trend—that is, it generates thoughts and actions leading in some definite direction. The traumatic complexes in the hysterical subject are immiscible with the personality. He refuses to accept them, and instead of abreacting—and thus normally getting rid of them—he either "converts" them, whereby the emotional (affect) excitement brings about abnormal innervation, which is exteriorised as the various hysterical manifestations; or he "transposes" the effect through indifferent ideas with the result that "anxiety neurosis" arises. The affect thus remains shut in or hidden in the unconscious. His principle of "overdetermination" is the same as Cajal's physiological concept of "avalanche" action, and expresses the heaping action of an affect sufficient to determine the appearance of a symptom.

The term "conflict" is used for the immiscibility above mentioned and also for the condition in which two complexes, tending to produce effects which are out of harmony, or even in direct opposition to one another, are simultaneously present in the mind. The conflicts will mutually inhibit one another, and the mind is divided against itself. The conflict may be avoided by volitionally banishing one of the opposing from the mind, and forgetting its very occurrence. If this process is successful, a condition of "repression" is attained. The affect of the repressed conflict is shut in to the unconscious mind, and there remains active to pervert the physical action of the higher nervous system. To cure the patient, this buried complex has to be raised again into memory, and its affect again raised into memory by the process of "psycho-analysis."

It is a general opinion that Freud's attention has been too much and rather one-sidedly centred upon psychic trauma of a genital nature, but it is fair to remember that he uses the term "sexual" in reference to the instinct of race propagation, and not necessarily to matters of sensuality.

As White has clearly put it, the characteristic of the psychic traumata which produce hysteria is their large content of painful affect. A painful affect fully reacted to at the time may do no harm, but if for any reason reaction fails, the feelings become repressed and the possibilities of dissociation are created. Failure of reaction may be due to conditions which make reaction impossible: as an instance, an insult is "swallowed," a dear friend is lost; and no compensation is possible, this giving rise to "retention hysteria."

Again ideas, usually of a sexual nature, which are incompatible with the personal consciousness, are repressed. This produces the "defence" hysteria. Freud's general hypothesis is extremely able and intricate, and little justice can be done to it in the space here at disposal.

Symptoms.—Mental State.—In a majority of hysterical patients there is considerable mental abnormality, and this sometimes presents marked characteristics, which differ in their detail according to the ever-varying peculiarities of individual character. The mental state is always reduced, with a relative exclusion of the environment and perhaps an elevation of the consciousness of self. This reduction in severe cases may amount to mental dulling verging upon amentia. There is defective will-power, imperfect self-control, and inability to resist the impulses of inclination. Self-consciousness dominates more or less completely the thoughts and actions, and finds its expression in glance, manner and tone. Upon the emotional side, there is a tendency to depression, which is often very dominating and prolonged in male hysterics. At the same time there is lability of emotional life. The mood is constantly changing. They are readily hurt, have little emotional control, and are easily dominated by ideas, fears, desires, and by sense of injury. There is often obvious exaggeration in the description of the sufferings, and the sympathy that is excited is a source of gratification to the patient, and there is almost always marked suggestibility. It is doubtful, however, whether the feeling of emotion is increased in the consciousness of the patient. Probably it is greatly reduced, although the expressions of emotion may be excessive. The psycho-galvanic test reveals a very interesting difference in this connection between the normal person and the hysterical patient. If electrodes are applied to the surface of the body and joined up with a galvanometer and resistance circuit properly balanced, and some emotion-exciting stimulus, such as the unexpected firing of a pistol, or a painful stimulus, physical or mental, is presented to a normal individual, there is at once a lowering of the resistance to the passage of the galvanic current through the body, which is shown by a deflection of the galvanometer. This is known as the psycho-galvanic response. In the hysterical subject this response often fails or is much reduced. A severe hysterical attack has occurred in a patient as this test was being made, yet notwithstanding the violence of the apparent emotion, the physical reaction above described, which occurs in all normal people upon emotion, absolutely failed to appear.

Disorders of Vision.—Unilateral blindness is not infrequent, but bilateral blindness is rare, and hemianopia is very rare indeed, but it does occur, and I have seen it produced by suggestion. The peculiarities of this loss of sight are that the pupils are normal in size and reactions, the optic discs are normal, and a feint made towards the blind eye or blind field often produces a quite normal wince of the orbicularis, especially if the patient is unaware that the feint is going to be made. Sometimes the loss of sight is not complete, and the complaint is of mistiness of vision or that objects can be seen but not recognised. Limitation of the field of vision is very common. It never takes the form of a scotoma or sectorial defect, and, therefore, such losses are always signs of organic disease. There is usually concentric contraction of the fields in both eyes, more marked in the eye of the anæsthetic side when hemianæsthesia is present. This condition is known as "crossed amblyopia."

The associated contraction of the colour fields takes the reversed order to that observed in optic atrophy. When the crossed amblyopia is severe, the fields may be restricted almost to points, and the colour vision is always lost first in the most affected eye. In testing the visual field, it often becomes smaller and smaller during the test, so that the perimeter tracing shows an ever-diminishing helicoid. Sometimes the opposite condition of an expanding helicoid is found—in other words, the observer gradually removes the defect by suggestion during his examination of the fields. Spasm of accommodation is common, and is usually accompanied by converging spasm of the globes, which may be intense. Severe converging spasm is rarely of any but hysterical origin. Sometimes the spasm is divergent, and there may be dissociated movements of the eyes. The squints have the contradictory features of being inconstant, increased by examination, and unassociated with diplopia. Micropsia and macropsia may occur. Ptosis is often seen and is usually bilateral. Blepharospasm is common.

Disorders of Hearing.—Deafness may be unilateral or bilateral, and when the latter it is usually associated with mutism. Hysterical deafness disappears during sleep, and a sound that is only sufficiently loud to waken a normal person will awaken those hysterically deaf; but when once awake they cannot be made to hear.

Disorders of articulation are very common in hysteria which has its origin in sudden fright. Mutism is the condition in which there is total inability to speak, though the organs concerned are used naturally for other purposes, as in mastication, clearing the throat, and coughing. Aphonia is the inability to produce the laryngeal element in the voice, and the patient always speaks in a whisper. Laryngoscopic examination shows that the normal movements of the cords do occur during the whisper, but the cords are not sufficiently approximated to produce a sound. Stammering is very common indeed in the traumatic cases. Recurring laryngeal, pharyngeal and buccal noises are troublesome features in some cases. The commonest variety is “hysterical cough.” The sound of birds or of animals may be imitated.

Disorders of Sensibility.—Sensory loss often accompanies hysterical paralysis, but it may exist alone and is occasionally entirely wanting. It is one of the most constant signs of hysteria, and it has the peculiarity that it is often unknown to the patient, whereas in organic disease the patient is usually aware that he cannot feel in the affected region. The common loss is to all forms of sensibility, but there may be loss to painful and thermal stimuli with retention of touch. The loss may be complete or partial, but even when apparently complete the patient can always be made to feel a strong faradic current applied for long enough. It may have any sort of distribution, which may vary from day to day, or it may be universal. The distribution is commonly hemiplegic and limited exactly by the middle line, or paraplegic, and when existing upon the limbs alone is often of stocking and glove pattern. Its limits are never exactly those of nerve trunk, nerve root, or of spinal segment sensory loss. The sensory loss is often of the greatest value in the diagnosis of hysteria, for it never has the correct distribution for organic disease. The “stocking” and “glove” loss may superficially resemble that of polyneuritis and subacute combined degeneration, but it has abrupt limitations proximally and is not deepest in the extreme periphery, fading off towards the trunk, as in these maladies. Janet's

test in determining the functional nature of sensory loss is often of value. If the patient is told to say "Yes" when touched and "No" when not touched, it will frequently happen that the answer "No" is given as often from the anæsthetic region as is "Yes" from the æsthetic region. It is difficult to bring this test off a second time upon a patient, for, thinking over it, he realises the discrepancy. Hysterical sensory loss sometimes involves the mucous membranes, and loss of smell and taste are common in conjunction with hemianæsthesia.

HYSTERICAL PARALYSIS.—Almost any part of the voluntary musculature of the body may be affected, and the disability may be slight or severe, but there is not often complete paralysis of the whole of a limb. In the slighter forms there may be weakness and tremulous movement. In the more severe forms the paralysis may be flaccid or spastic. The flaccid variety is the less common, and is usually of rapid onset and is almost invariably associated with complete loss of sensibility over the affected region. There is a limp, flaccid condition of the affected muscles, which are not wasted, and the electrical reactions are normal. The limb may be passively moved in all directions without discomfort to the patient, and hypotonia is not present and, indeed, as judged by the unvarying briskness of the tendon reflexes, the muscular tone seems to be increased. The paralysis is entirely one of volitional movement. As examples: when the shoulder is completely paralysed, yet the latissimus dorsi contracts well on coughing. Or, when the leg is paralysed, if the patient be commanded to sit up in bed from the supine position, with the hands folded across the chest, the paralysed leg remains stationary upon the bed, while the normal limb rises in the counterpoise action of the associated movement—that is to say, the paralysed limb is kept upon the bed by active contraction of its muscles; this phenomenon contrasts strongly with what is seen in organic hemiplegia, where, in the attempt to sit up, the paralysed limb rises much more than the normal limb.

More commonly hysterical paralysis is associated with stiffness of the muscles. Here the muscles are not wasted, and they may be hypertonic, as shown by the briskness of the tendon jerks and by the presence of foot clonus. The voluntary paralysis is less complete than in the flaccid type, some movement being usually possible, and this movement invariably shows the contraction of the antagonists before the prime movers in the movement commanded. If the patient is commanded to flex the elbow strongly while the triceps and biceps are palpated by the hand, the observer will feel first a strong contraction of the triceps—as if to prevent the movement commanded, followed by a feeble contraction of the biceps. From the prior action of the antagonists and their subsequent struggle with the prime movers, the movement in the paretic region shows a peculiar broken quality, which hardly occurs in any other condition and which may be considered pathognomonic of hysterical paralysis.

It is a usual feature of hysterical paralysis that when the patient is commanded to perform an act, he shows great outward signs of effort in the way of struggling and contortions—in any or every part of the body, except in the region commanded; with rapid breathing, sweating and every outward sign of emotion and subsequent exhaustion. It is also characteristic that the hysterical patient does his worst when commanded to use the affected regions, with much spectacular show, whereas the patient with organic paralysis

obviously does his best without any such fuss. The affected region is held stiffly from active muscular contraction, but there is no true spasticity, as is shown by the fact that if an affected hand be passively flexed at the wrist, there is no relaxation of the flexor tendons, such as always occurs in organic spasticity. When rigidity is marked, the limbs may show fixed attitudes, which are termed "contractures," and these may simulate organic spastic contractures; *pes cavus*, however, which is one of the commonest of organic contractures, is never simulated in hysterical contracture. The contractures are often characteristic of hysteria. In the upper extremity, the usual contracture is flexion of the elbow, wrist and fingers, with adduction of the arm to the side; but the fingers are sometimes extended and adducted, with the thumb across the palm, as in the "interosseal" position. In the lower extremity, the position is usually one of extension at the knee, with the foot dropped and inturned to an extreme degree. Flexor contracture at hip and knee are, however, sometimes met with. It is highly characteristic of nearly all hysterical contractures, and highly distinctive from organic contractures, that passive movement to overcome the contracture is productive of great emotional disturbance, which even the patient himself does not ascribe to any pain produced by the manipulation.

In distribution the paralysis may be monoplegic, hemiplegic, or paraplegic, or it may affect eyes, face, tongue, or trunk alone. Affection of the face is very uncommon. When the leg is affected on one or both sides, the gait is entirely unlike any gait seen in organic disease. Sometimes the feet are shuffled along the ground, no attempt being made to raise them or to swing them round in the fashion common in organic spastic paralysis. Sometimes the gait is obviously "constructed," and at once suggests the diagnosis of hysteria.

In severe cases, the feet are dragged more or less helplessly, with the dorsum resting upon the ground, and the soles looking upwards and backwards. It is unusual for the patient to fall when walking, unless he sees means of saving his fall, or has something comfortable to fall on. Hysterical spasm of the tongue may be seen, alone or as a part of a hemiplegia. The tongue is turned over to one side, often to the wrong side, and its appearance is unlike that produced by organic disease. Hysterical paralysis of the trunk muscles often results in most remarkable curvatures and deformities of the spinal column and trunk, which may simulate spinal caries and scoliosis and the paraplegia which either of these conditions may entail. This is one of the two common forms of "hysterical spine," the other being a painful condition, with local tenderness.

In every form of hysterical paralysis there is a complete absence of all those signs which we hold to be proofs of the presence of organic disease, such as wasting and change in the electrical reactions of the muscles, loss of the skin reflexes of the trunk, the extensor plantar response, loss of sphincter control, loss of knee-jerks, etc. Brisk tendon jerks and foot clonus are not signs proving organic disease, for these often obtain in the normal subject, and they are commonly found in hysteria. The plantar reflexes are often absent in hysteria, both when sensibility is normal and when it is lost.

Among the innumerable symptoms which may be present in hysteria should be mentioned the sensation of a lump in the throat—the "globus hystericus." Difficulty of swallowing may occur, presumably due to spasm

of the œsophagus. The food, though swallowed, may be again rejected before it has passed the œsophagus. Vomiting often occurs, and is sometimes severe, and may end fatally, with emaciation and acidosis. When dull and depressed, the hysteric is often antagonistic to food, and nasal feeding may be required. Air swallowing may lead to alarming abdominal distension, with severe general symptoms, and it is no uncommon experience to meet with a hysterical patient who has had more than one laparotomy performed for the relief of urgent symptoms so produced.

Alteration of thyroid function, in the form of relative hyperthyroidism, with fine tremor, tachycardia, sweating and even some degree of retraction of the lids, was very common in the military cases. Subnormal blood pressure is almost invariably present. Vasomotor and trophic changes may be met with in the paralysed regions, especially when the condition is of long standing. Relative cyanosis and œdema may occur, sometimes in patches, and these signs were referred to by Charcot as the "blue œdema" of hysteria. Changes in the joints, such as fixity and fibrosis and thinning of the skin, with "satin" change and wasting of the subcutaneous tissues, is sometimes seen in the fingers, where the nails may also be "reeded." All such changes are more common when there is much rigidity, and are explicable, at least in part, by the impediment to the blood and lymph circulation which unvarying rigidity of the muscles and immobility of the limb entail.

TREMOR.—This is a very common symptom, and it often accompanies the paralysis and contracture. In its slight forms, it is seen as the broken movement which occurs when the affected limb is moved upon command. It is not often constant, but is usually evoked by movement and excitement. It is usually a fine quick tremor, varying in degree and in time, always increased and sometimes distinctly induced by attention, and when the mind is diverted the tremor may cease. Occasionally it may simulate the tremor of paralysis agitans or that of disseminate sclerosis so closely as to deceive at first sight. Hysterical tremor, widening in range into what deserves the name of clonic spasm, may come in paroxysms under the influence of emotion, and may easily pass over into an hysterical fit.

HYSTERICAL FITS.—Just as emotion is naturally expressed by muscular actions, as in the dancing for joy of a happy child, the stamping with rage, and the wringing of the hands in distress, so the violent emotional discharges in hysteria may take the form of paroxysms of movement, always spectacular and impressive, but never occurring without the presence of an audience, and never occurring in a condition of sleep. Such attacks often have an exciting cause from within or from without, and, commencing perhaps mildly, work up into violence, which may be extreme. Rigid fixation of the trunk and limbs, often with such a degree of opisthotonus that the body is supported upon occiput and heels alone, alternates with wild movements, in which the limbs are thrown about with great force and rapidity; the arms strike out, the legs kick, and the head is dashed from side to side. The hair and clothes may be torn, the lips and limbs bitten, and any forcible attempt to restrain the patient increases the fury of the attack, whereas complete neglect, as by the departure of the audience, often causes the attack to cease abruptly. These phenomena may alternate with quiet intervals, often attended with hallucinations and delirium. Consciousness may be lost, and is often much perverted, and usually the patient retains no recollection of the

fit. The face may be deeply reddened by holding the breath, but there is not the pallor nor the cyanosis of the epileptic attack. There is never conjugate deviation of the eyes, but there is often severe converging spasm. The corneal reflex is retained. The pupils may be dilated, or, when there is converging spasm, contracted; but they always react to light. The eyes are passively opened with difficulty, for the patient resists. The tongue is rarely bitten, though the lips and cheeks may be. The pulse is quickened, but there is never that imperceptibility of pulse at the onset of the attack which characterises epilepsy. The movements are always purposive, and do not show any definite sequence of tonic and clonic spasm. The tendon jerks and plantar reflexes are unaltered. There is never incontinence of sphincters. There is usually marked diminution of sensibility and a disordered gait after the attack. The attack may cease abruptly, and there is not the apathy, headache and sleepiness thereafter which are so frequent in the epileptic attack. The hysterical attack can often be cut short by supra-orbital pressure, or by faradism, or by the application of cold water. These points will serve to distinguish the hysterical attack from the pure epileptic attack; but it must be carefully borne in mind that the post-epileptic hysterical attack differs in no way but in the associated circumstances from the purely hysterical attack.

Diagnosis.—The general features of hysteria are so definite as to cause little difficulty in diagnosis to the medical man who is conversant with them, and who appreciates the necessity of considering every case to be one of possible organic disease until he has convincing proof that it is one of hysteria. A most scrupulous search should be made throughout the organs of the body for signs of organic disease. For in some organic diseases of the nervous system the early signs may be reasonably suggestive of hysteria; they may come on suddenly as the result of emotion or shock, and may disappear rapidly, and, when at their height, may show little in the way of definite organic quality. Especially may this occur in disseminate sclerosis, and also in subacute combined degeneration, cerebral tumour, and many other organic conditions. A further difficulty is introduced by the fact that the presence of organic disease may determine true hysterical manifestations, and thus hysteria may be coupled on to organic disease. When no organic signs are present, due weight must be given to any history of previous signs of hysteria, to any causal factor which may have a powerful emotional effect, and to the age and personality of the patient. Often the nature of the paralysis and disability, and the presence of other associated signs of hysteria, are so evident as to leave no possible doubt; such as the distribution of the paralysis and of the anaesthesia, which no possible organic lesion could cause, the non-correspondence of paralysis with sensory loss, the prior contraction of the antagonist muscles and the broken movement, the contradictory phenomenon, the peculiarity of the contractures, and the often fantastic "constructed" gait, the unilateral blindness, the crossed amblyopia, aphonia, and the vomiting. The chief difficulty in diagnosis is the distinction of the early signs of organic disease from those of hysteria, especially the early manifestations of disseminate sclerosis, and this difficulty can only be overcome by the discovery of some definite organic sign of the disease, either in the previous history of the patient, such as transient diplopia, amblyopia, or dysuria, or the occurrence of similar attacks of paralysis in other parts of the body; or

the presence of some slight though suggestive sign at the time of examination, such as nystagmus, slight intention tremor, inequality or loss of the abdominal skin reflexes and the extensor response in the plantar reflexes.

The diagnosis of hysterical fits from epileptic, vaso-vagal and syncopal attacks depends upon a consideration of the circumstances of the occurrence of the fit and upon the manner of the fit. These have already been considered, and are also referred to in the description of epilepsy. Certain valuable points in distinguishing hysterical hemiplegia from that of organic origin are here placed in the form of a table :

	Hysterical.	Organic.
Vision	Unilateral blindness, or restriction of field, or crossed amblyopia.	Hemianopia or blindness of opposite eye or central scotoma.
Sensory loss	Hemianæsthesia, or stocking and glove loss, often deep.	Hemianæsthesia only, usually slight.
Face	Never paralysed ; sometimes shows spasm.	Often paralysed.
Paralysis	Rarely complete.	Often complete.
Gait	The toes are dropped and the foot is dragged behind, or the gait is constructed and fantastic.	The foot is swung forward in a half circle.
Contracture	Knee usually extended. Foot dropped and inturned.	Knee often flexed. Foot : pes cavus.
Abdominal reflex on paralysed side	Brisk.	Diminished or lost
Plantar reflex	Absent or flexor.	Extensor.
Thigh phenomenon on sitting up	Absent.	Present.

Course and Prognosis.—The manifestations of hysteria, however severe, are practically without danger to life, for it is only a few cases that succumb to vomiting and its results. The disease is eminently curable and often permanently so, the difficulty being, when a cure is not permanent, that the ordering of the patient's life as regards the necessary education, occupation, satisfaction and achievements is not in the hands of the physician. The course of the disease is very varied and is often marked by partial recovery, followed by relapses. The symptoms may disappear suddenly, sometimes as the result of impressive therapeutic measures, sometimes without any definite cause. Such rapid recovery is more common in cases where the symptoms have been of short duration, but it is not to be dismissed as impossible, even in cases of very long standing. More often gradual improvement occurs, and the symptoms take weeks or months to disappear. The prognosis is worse, as regards rapid recovery and the occurrence of relapses, when the general signs of the disease are well marked, when the general conditions of health and nutrition are poor, when there is much mental dullness which prevents the patient from being dominated by his physician, and while litigation is in progress over compensation claims. It is also worse the longer the symptoms have been present. Yet I have witnessed complete and lasting recovery to occur rapidly after almost complete paraplegia had caused a patient to be bedridden for seventeen years. Practi-

cally all the cases ultimately recover so far as paralysis is concerned. The prognosis is rapidly favourable in proportion as definite causes can be traced and removed, and as adequate measures for treatment can be applied in good time.

Treatment.—1. *General.*—Where bodily nourishment is poor, and there is feebleness and exhaustion from overwork, stress or any other cause, those measures calculated to better the condition and to increase weight should be employed. Rest in bed, with a liberal mixed diet, is essential. Tonics, especially the combination of strychnine and bromides, are most useful, and due attention should be paid to securing adequate sleep. Removal from the usual surroundings and treatment in a hospital or institution, where isolation from business matters, friends and relatives can be secured, is highly advantageous. I never isolate my hysterical patients, but prefer to treat them in a general ward, where the scene enlivens and prevents boredom, and where the atmosphere of every patient getting better immediately brightens the prospect for the patient and enhances the curative power of the measures employed.

2. *Rapid cure by suggestion.*—The essential method of this treatment is for the suggestor to secure the profound liking and confidence of his patient, and so dominate his personality that he dare not disobey. The patient is brought into that frame of mind in which he both desires and expects to be cured. Those who have recently passed through great strain and those who are mentally dull are best kept at rest for some considerable time. For them to be kept waiting to be cured often brings about a useful increase in the desire and expectancy for the result. In this preparation for rapid cure, nurses skilled in this method often play so important a part as to make the final cure by the physician a matter of complete simplicity. When the decision has been made that the time for treatment is ripe, the suggestor demonstrates to the patient that he can feel and move the affected region, and that he can do so normally and continuously, and that his malady has disappeared. This task should be undertaken with determination on the part of the suggestor and agreement on the part of the patient, that however long the sitting, a completely successful issue must be brought about before it is ended. In one particularly difficult case which was under my care, which was of long standing, the most able curer of hysteria that I have met commenced his sitting at six o'clock one evening and carried it on continuously through the night, giving the patient no rest whatever until well on into the following day, when a complete and permanent disappearance of all the symptoms occurred. This treatment necessitates infinite resolve, energy and patience, and boundless resource and confidence on the part of its applicator, who must dominate, insist, cajole and bully the patient into complete discipline to his commands and instructions, without ever losing his temper, without ever losing the esteem of his patient, and without ever failing. The precise method of suggestion is immaterial so long as it is strong enough, and the line of treatment must be varied according to the mental attitude of the patient. All of us have to use those methods which suit our personalities and which we individually find successful. We should fail with those methods which others find successful. Some of us cannot storm with dignity, nor bully and cajole with patience and assurance. Others find it impossible to cure hysterical patients by any rapid method.

Paradism with a strong current is a useful adjunct in suggesting the return

of sensibility and in initiating movement. The suggestor gets rid of the sensory loss first, before proceeding to attack the paralysis. Such aids as electricity may not be necessary to a physician who is endowed with more than the ordinary personal force and powers of persuasion. As simple examples of this method of treatment, an electrode, placed upon the posterior wall of the pharynx in a case of mutism and set alive, will cause the patient to shout "ah." The electrode is withdrawn and he is commanded to say "ah." Having thus demonstrated to him that he can make a sound with the larynx, he is persuaded and re-educated to talk. Similarly, when there is paralysis in the foot, faradism is applied to the popliteal nerves, and the patient is commanded to watch the movement. He is then persuaded to make the same movements voluntarily. This rapid method of treatment has, under my observation, proved unvaryingly successful in the hands of every adept administrator, and it seems only to fail in those few cases in which there is mental dulling, and inability of attention and interest, and should, therefore, not be applied so long as a patient is in this condition. The remarkable change which takes place in the mentality, feeling of well-being, appearance and manners of the hysterical patient as the immediate result of this rapid method of cure is striking.

3. *The psycho-analytical method.*—This is the logical outcome of Freud's theory of the genesis of hysteria. Its aim is to determine the repressed complexes, the effect of which in the unconscious mind is interfering with the physical working of the brain. They are raised into conscious memory by the analysis and so freed from exerting their baneful influence, are freely discussed between the patient and his physician, and are interpreted by the latter. The result is a purging of the mind and a disappearance of the paralysis. I am sure that the success attending the use of this method depends largely upon the personality of its applicator.

NEURASTHENIA

Definition.—A condition of pathological weakness without discoverable lesion, manifest by too rapid and too great fatigue, physical or mental or both together, and by a loss of bodily and mental comfort which the normal person possesses, by emotional unbalance, and by undue irritability and too great a response to some stimuli in the nervous system. Bodily sensations are often abnormal, and tend to loom into consciousness unduly and to absorb the attention immoderately. There is disability or inability, rather than perversion, of function.

There must be few people who have not experienced such a train of symptoms as the above, whether during recovery from acute illness, or as the result of overwork, grief, or disappointment, or following upon physical and mental shocks. But usually the defective physical processes which allow of the development of these symptoms soon return to the normal, and the symptoms are transient and soon forgotten. If, however, the physical processes be congenitally defective or weak, or if they are so affected as not easily to return to the normal, or if the factors are continuing, then this train of symptoms may be lifelong, or may be recurrent, or it may require special measures of assistance for its eradication.

Ætiology.—Neurasthenia may be prenatally installed, and it may run in families. The congenital cases, which have been termed “primary neurasthenia,” usually show symptoms throughout childhood, which become aggravated as life goes on. No age is exempt, but the malady is very rare in childhood. It appears more commonly after puberty, but has its greatest incidence in the third and fourth decades of life, when the stress, responsibilities and disappointments of life come to their full, and continues common so long as these are borne, diminishing almost to a vanishing point in old age. It is rather more common in men than in women. Neurasthenia may arise without any discoverable causal factor in cases which are certainly not congenital. The common factors are: (1) Any conditions of physical ill-health whatsoever which may lower the vitality of the nutritional processes. (2) Any conditions of education and upbringing which tend to render the subject unfit to cope with his environment in life. (3) Absence of occupation, scope, satisfaction and outlet in life. (4) Physical overwork. (5) Emotional stress of every kind is a much more important cause than overwork, according to the old saying that “it is not the work but the worry which kills,” and consequently those occupations which involve work at high pressure cause more of the workers to break down with neurasthenia. (6) Sudden physical shocks and frights are potent causes, especially such as may occur in times of war, from bombardment, high explosives and aerial attacks. (7) Continued conditions of fear, such as may occur after syphilitic infection or after breaches of the law.

NATURE OF NEURASTHENIA.—The causation of the malady being concerned either with a congenital defect or with emotional disturbances with their provedly potent effect upon endocrine function and metabolism or with exhaustion conditions, it is reasonable to regard the essential defect as a metabolic error in which, from perversion or failure of chemical processes, the normal activation of the physical organs is defective or perverted. This perversion may be lifelong, as in the congenital cases, or may be very rapidly transient, as in the debility which may follow acute illness, or after reaching an extreme degree may return to the normal permanently. As regards the nature of the change or what organs are at fault we are entirely ignorant. It has been shown experimentally that animals exposed to repeated frights, as from bombardment, develop neurasthenia or “shell shock,” just as do human subjects. Again, some animals in captivity present that listlessness, restlessness, inattention, sexlessness, negativism and emaciation, often ending in death, in the absence of organic disease, which can only be described as identical with the symptoms of neurasthenia. It is amazing, on the other hand, when we consider how many people pass their lives in conditions of ill-health, overwork, repeated child-bearing and harassing troubles and yet never lose a sunny temperament, a cheery optimism, and a boundless energy.

Symptoms.—The onset is never sudden, though there may be an acute outburst of symptoms at any time. Even in traumatic cases, the symptoms take a few days to appear and thereafter increase in intensity. They commence with feelings of weakness and exhaustion, and a loss of the sense of well-being, and as the days pass fatigue, both physical and mental, occurs after less and less effort, mental depression follows, and every sustained effort becomes burdensome. Mental effort too becomes difficult, and there is

especial trouble in concentrating. Interest either in work or in pleasures fails. Fatigue once produced does not pass away rapidly with rest, as in normal persons, and even sleep brings no refreshment. The sufferer is apt to sink into a monotonous condition of irritability and depression, with no desires or incentives, thinking only of himself and of his misery. He loses pride in his personal appearance, and quite commonly neglects the ordinary rules of personal cleanliness. He has lost the ordinary reactions, both of pleasure and of grief. Events may occur which satisfy the whole ambition of his life's work and arouse in the neurasthenic subject hardly a passing interest, or he may suffer the loss of one nearest and dearest to him with a selfish indifference which is hardly human. The appetites tend to fail, and sexual power is low or may remain entirely absent throughout the course of the disease. In the worst cases, continuous thought becomes impossible, and any continuous action equally so, and this often engenders a bedridden life. The difficulty of thought and concentration adds the fear of mental breakdown to the patient's misery, and he often has causeless terrors of impending evil or ruin. He cannot bear to be alone, or in a crowd. He cannot bear to be in a closed space, or he has the terror of death when in an open space. To remove him from his home and friends will make his illness irrecoverable. To cross the road alone is too dangerous for him. Such "phobias" may be multiplied indefinitely: claustrophobia (closed space) and agoraphobia (open space) are two of the commonly occurring varieties. There is never any serious change in the moral sense, and the neurasthenic patient is never led by his illness into acts of shameless crime or even to slight infraction of the moral law; but he is apt to become peevish, fretful, fault-finding, and supremely and childishly selfish and unreasonable. Nor does the neurasthenic person in my experience often fall into drug addiction. For the most, he is hopelessly valetudinarian according to his lights.

Paræsthesia.—Sensations of bodily discomfort are always present, and these may be vague and general or they may be localised. When vague and general, they may be both described and explained by lack of the feeling of bodily comfort which we in health possess—the satisfaction after a meal, the comfortable tiredness after healthy exercise and the pleasure of repose, the exhilarating feeling which accompanies work done and pleasures enjoyed, and which the anticipation of events brings. The feeling of fatigue is distressful, the body vaguely aches in general, and comfortable repose is out of the question. Cephalic sensations are the most usual of the local paræsthesias. These are described as a sense of weight or pressure upon the head, or as an aching tightness, especially apt to affect the back of the neck, and they come on with any effort, mental or physical. They are never described as pain, but as something worse and less bearable than pain. As a matter of fact, the neurasthenic patient bears actual pain with more fortitude than does the normal subject, and will sometimes volunteer that pain relieves him. Spinal discomfort, in the form of the back which always aches and is never out of consciousness, is frequent. Abdominal sensations are so usual as to have given origin among the ancients to the term "hypochondria."

Circulatory disturbances.—The blood-pressure is invariably low. I am of opinion that a high blood-pressure is incompatible with the development of neurasthenia. The low blood-pressure often entails sensations of giddiness, especially on sudden alterations of position, and is perhaps respon-

sible for the cold, moist, bluish skin often seen in the extremities, and for the facial pallor and unhealthy appearance.

Some of the patients, particularly those of the traumatic group, may show definite signs of hyperthyroidism, and perhaps tremors occurring in this disease are always of this nature. I have seen every gradation between a pure neurasthenia and a definite Graves's disease. Loss of appetite is usual, or the appetite may be capricious—to-day ravenous and gone to-morrow. Discomfort after meals and anorexia are frequent, and when severe may lead to great emaciation, such as may seem only compatible with serious organic disease. There is more or less insomnia, or distressful dreams and nightmare, after which the patient awakes still more weary and depressed. The morning is the worst period of the day with all neurasthenic subjects, and sometimes as the day goes on life becomes relatively tolerable. Neurasthenia is not infrequently associated with hysterical manifestation, which is not surprising, considering that so many causal factors, such as emotional upset, overstrain, fright, injury, etc., are common to the two diseases. In some cases the symptoms of these two conditions are so intimately blended that the patients might with equal justice be placed in the category of neurasthenia or of hysteria.

There are no objective signs in the nervous system, and the presence of any such signs should at once call into question this diagnosis. Every degree of the disease may exist. The slighter forms when transient are often expressed when we are tired out, overwrought and want a holiday; and when permanent, pass as individualities of temperament, or as gloomy, irritable and complaining disposition. The subjects of the slighter forms, especially of congenital neurasthenia, may be capable of very brilliant work and accomplishments. In its severest forms, neurasthenia may lapse into a condition in which all effort, mental and physical, becomes impossible, and the patient is bedridden and practically amentic. In this state there may be much negativism. Food is often refused and there may be constant vomiting, and the dejecta may be passed into the bed.

The term "psychasthenia" is in frequent use for those cases in which the manifestations are upon the mental side only. As every gradation occurs between these cases and those in which the symptoms are mainly physical, there seems to be no reason for regarding psychasthenia as other than a variety of neurasthenia.

Diagnosis.—With reasonable care and a sufficiently broad outlook, the diagnosis of neurasthenia presents no peculiar difficulties, except in the possible vagueness of the early symptoms. For the causes are, as a rule, definite and conspicuous, and the symptoms when well marked are pathognomonic, and there is a complete absence of any organic sign. Before entering upon a diagnosis of this malady, it should be fully realised that the loss of bodily feelings of well-being, and the easy fatigue and incapacity which characterise it, may be expressions of many organic diseases, and that these are also very prevalent as early symptoms of mental diseases. A careful search should therefore be made not on one occasion only, but repeatedly, for signs of organic disease. Addison's disease, when occurring in a fair subject without conspicuous pigmentation, has been repeatedly mistaken for neurasthenia, but can be at once distinguished by the extremely low blood-pressure. Any occult disease which interferes with bodily metabolism may produce neurasthenia-like symptoms. Those concerned with life assurance

are of opinion that tuberculosis in its earlier stages, and under the name of neurasthenia, often comes before them, but from the side of neurology I have not come across this error in diagnosis. Tumours of the brain, when involving the frontal and the temporal lobes, may cause little in the way of general intracranial symptoms, but marked symptoms of inattention, dullness and incapacity such as may be attributed to neurasthenia. The distinction here is to be made by repeated examination of the optic discs for definite signs of intracranial tumour. General paralysis of the insane often commences with depression, bodily discomfort and incapacity for sustained exertion. Examination of the blood and cerebro-spinal fluid will settle the diagnosis. The distinction for the early stages of chronic insanity may be so difficult as to be well-nigh impossible. The circumstances of the individual case and the presence of a definite cause for neurasthenia are important aids. The presence of exaltation and grandiose states excludes neurasthenia, for no neurasthenic is ever exalted or grandiose. Moral degeneration, as shown by shamelessness and criminal acts, always excludes neurasthenia, as does also any definite delusion. The distinction from hysteria is simple, for the symptoms of the two maladies are quite different. They, however, frequently coexist.

Course and Prognosis.—In all cases except the congenital ones, the prognosis as to both life and cure is good, and even when the disease is congenital it may be greatly benefited. Many men and women are mildly neurasthenic for years, and yet do their duty in the world, and not infrequently a great work. Much of the world's work has been done by invalids, many of them congenital neurasthenics. The usual event is gradual improvement so soon as removable factors can be eradicated and appropriate treatment applied. In the neurasthenia which may follow acute illness, recovery is usually rapid and permanent. The danger of recurrence is considerable where causal factors remain active, in congenital cases, and in the cases in which there have been many previous breakdowns.

Treatment.—*Prophylactic.*—Those children who may be handicapped by a defective heritage should be guarded during their development by the paying of strict attention to moral and physical hygiene, and to education, discipline and occupation. When later they enter actively into more strenuous work, limitation of mental and physical exertion should be insisted on, and anxiety and worry avoided. Healthy sports of all kinds are advantageous. In cases in which grief, fright or accident has severely shaken a person, rest and quiet with careful attention to nutrition, and an abrogation of all work and responsibility and the securing of adequate sleep, are certainly measures likely to avert neurasthenia. This prophylaxis is too often omitted after accidents and injuries, and when applied it should not be discontinued too soon.

Curative.—Rest, both physical and mental, the securing of peaceful sleep, the restoring of appetite, careful feeding, and the administration of stimulants, in the form of strychnine, glycerophosphates and thyroid preparations, together with the bromides, which by cutting off the edge of the discomfort lessen the distress, are the most important measures. The patient always improves more rapidly when nursed by strangers knowledgeable in his malady, and away from his own home. But isolation as laid down in the Weir-Mitchell treatment is strongly to be deprecated, except in rare

and special cases. Far better surround him with a wise, sympathetic and changing audience, to whom he can lay bare his troubles, and who are able to take his mind from himself. Again, the nature of the rest to be ordered is a matter for careful consideration. In exhaustion conditions, complete rest in bed is grateful to the patient and should always be adopted. To some people, however, idleness is torture, and to give them rest you must give them something to do. Inanition is one of the chief perpetuators of neurasthenia, and some cases are only to be cured by putting them back to work by degrees, and with encouragement and medicinal aid.

Massage is very useful in those patients who like it, and are soothed and comforted thereby. Its physical effect is important, and it serves both to pass time and to satisfy the patient that something active is being done for him. The personality of the applicator is, therefore, by no means negligible. To those patients who hate being touched and, therefore, dislike massage, it does more harm than good. Hydrotherapy and electrotherapy are useful, provided they are not distasteful to the patient. Organotherapy has been much vaunted and greatly employed. It is certain that all of the preparations which have been used, both orally and by injection, are stimulants of metabolism and, therefore, are useful. That they have any specific effect upon neurasthenia is far from proved. Some of them owe their value entirely to the thyroid content, usually very insufficient.

The patient should always be kept under observation and strict treatment until there is some sign of improvement. It is a mistake to order forthwith a change of air and scene when the patient is not well enough to make any advantage of it; often such a course will aggravate the malady. Once improving steadily, such measures are of great value, and in proportion to the joy of anticipation and the satisfaction that they may bring.

JAMES COLLIER.

LOCAL LESIONS OF THE SPINAL CORD

COMPRESSION OF THE SPINAL CORD

In compression the lumen of the spinal canal is reduced in a small part of its vertical extent, and the spinal cord is injured at this point, either directly by pressure, or indirectly by interference with its vascular supply. With the exception of acute inflammation of the membranes, all the extramedullary lesions of the spinal cord come under this heading. The characteristic clinical feature of compression is the combination of two sets of phenomena: local or root symptoms in those regions supplied by the roots arising from the cord at the level of the lesion, and remote or cord symptoms due to interruption of the conducting paths in the white matter. It is convenient to divide this subject into two parts—slow compression and compression of rapid onset.

SLOW COMPRESSION

The commonest causes are tuberculous spinal caries, vertebral tumours, meningeal tumours and cysts; rarer causes are aneurysm, gumma, leukæmia,

Hodgkin's disease, Paget's disease, syphilitic caries, spondylitis deformans, and other chronic inflammations of the bones and joints of the spine.

Ætiology and Pathology.—1. *Tuberculous spinal caries (Pott's disease).*

—Spinal caries is the most frequent cause of slow compression. It occurs most often in children, but is common in adults, and may begin late in life. Signs of injury to the cord develop in about 1 case in 20, and are usually preceded by obvious deformity of the spine; but in many cases they appear before disease of the bone is suspected. Rarely paralysis comes on for the first time in an adult who has had a curvature since childhood.

The cord may be damaged by direct pressure of displaced bone, or by an abscess beneath the periosteum of the diseased vertebræ; but in almost all cases the injury is indirect, and results from œdema of the cord, arising from interference with its blood supply by tuberculous granulation tissue, which forms on the outer surface of the dura mater and fills the epidural space (pachymeningitis externa). The functions of the cord may be temporarily deranged for long periods by this œdema, without permanent damage to the nervous tissues; hence, when the disease is cured, the œdema subsides and the cord recovers. In cases of greater severity necrosis of the nervous structures follows thrombosis of the vessels, or prolonged pressure causes atrophy of nerve roots, and complete recovery is impossible.

2. *Tumours of the vertebral column.*—Vertebral tumours are about twice as common as all the other forms of extramedullary tumours together, and almost all of them are malignant. Carcinoma is always secondary, and is a frequent and distressing complication of cancer elsewhere. A very small primary carcinoma, e.g. of the breast, thyroid or prostate, may produce extensive disease of the vertebræ, and signs of compression may appear before the existence of the primary growth is suspected. On the other hand, they may appear several years after complete removal of the primary growth, and may be the first evidence of a recurrence. Sarcoma, the commonest form of primary growth, begins in the bone or periosteum of the bodies or laminæ, often in several at once, or simultaneously at different levels. Secondary sarcoma arises by metastasis from sarcoma elsewhere, or by direct extension from a growth in neighbouring soft parts, e.g. of tumours in the mediastinal and retro-peritoneal spaces.

The growth of vertebral tumours is usually rapid, and extensive portions of the spinal column may be completely destroyed. The cord is compressed by the growth itself, by displaced bone, or by a process of the growth which invades the spinal canal through an intervertebral foramen. As a rule, the dura mater sets bounds to its inward extension. Benign tumours of the spine are rare. They usually grow forwards, but occasionally an osteoma, a chondroma, or an exostosis produces signs of compression.

3. *Meningeal tumours.*—These are divided into two groups—intradural and extradural. The first are twice as common as the latter, and more than half of them are simple, encapsuled, and easily removable. Myxoma, fibroma, sarcoma, endothelioma, and psammoma are common. Other forms are rare. In most cases they lie posterior or postero-lateral to the cord, and are seen when the cord is exposed by laminectomy; but in a few cases they lie in front and may escape detection.

Sarcoma is the commonest extradural tumour. It is sometimes encapsuled, but more often it is a diffuse growth difficult to remove.

These tumours usually grow very slowly, and several years may elapse between the onset of the first symptom and the time when an accurate diagnosis can be made. They do not invade the substance of the cord, nor penetrate the dura, nor give rise to metastases.

4. *Cysts*.—Cysts, parasitic and non-parasitic, may compress the cord and produce symptoms indistinguishable from those of solid tumours. In some countries hydatid cysts form a high proportion of all spinal tumours. They may invade the spinal canal from adjacent soft parts or from the vertebræ, or arise primarily in the membranes. They are often multiple, and are nearly always extradural. Cysticercus cysts, which are very rare, are usually single and intradural. Non-parasitic cysts are collections of fluid contained within slightly thickened adherent membranes. They are among the most frequent of spinal tumours. They are most likely a result of circumscribed inflammation of the pia-arachnoid, and have been known to follow an injury; but their ætiology is obscure. The cyst is often opened inadvertently during operation, and the only evidence of its former presence is flattening of the cord and atrophy of the nerve roots at the point where a solid tumour was expected. Sometimes the position of the cyst can be inferred at operation, from the absence of normal pulsation below it. On puncturing the membranes in this position fluid escapes under pressure, and the pulsations reappear. The name *meningitis serosa circumscripta* is applied to this condition.

5. *Aneurysm of the aorta* is a rare but well-known cause of spinal compression. The dorsal region is most often affected, three or four vertebral bodies being slowly eroded until the dura mater is exposed. Rupture into the spinal canal has been observed.

6. *Syphilitic caries*.—Gummata and caseous masses of syphilitic origin in the bones of the spine may cause a condition not unlike that of tuberculous caries. It is very rare, and usually occurs in the cervical region where the cord may be compressed.

Symptoms.—**EXTRADURAL COMPRESSION.**—*Local or root symptoms.*—Pain in parts supplied by the sensory roots arising from the cord at the level of the lesion is often the first symptom. It may be a dull ache, a feeling of constriction, a sharp cutting pain, or pain so severe as to be almost unbearable. It is often brought on or greatly increased by movement of the spine or by coughing. The skin in the painful area is sometimes hypersensitive at first, but very soon its sensibility is diminished, while the pains persist (*anæsthesia dolorosa*). The nerve trunks are not tender as in ordinary neuralgia. Severe pains are rarely absent in cases of vertebral tumour. In spinal caries they are usually absent or slight. Injury to the motor cells or anterior roots leads to weakness, wasting and loss of tone in the corresponding muscles. In some cases root symptoms are absent throughout the course of the disease, and the first effects of compression are referable to interruption of the conducting paths in the cord.

Remote or cord symptoms.—Although all the tracts are submitted to the same degree of compression, their functions are not impaired at the same time. While variations are common, the symptoms usually arise in the following order: first weakness and spasticity in the lower limbs, then im-

pairment of sensation, position and passive movement, temperature, pain and touch being affected in this order. Defective sphincter control often precedes and sometimes follows sensory loss.

Motor symptoms.—Interruption of the pyramidal tracts produces spastic paraplegia in parts below the lesion. The clinical features are—(1) diminution of voluntary power; (2) alterations in the amount and distribution of muscle tone and in the attitude of the limbs; (3) changes in the tendon and skin reflexes; (4) the occurrence of certain involuntary and reflex movements.

To understand the phenomena of spastic paraplegia it is essential to remember that the muscles of the lower limb are divided into two distinct groups—the flexors and the extensors—and that the muscles which dorsiflex the foot and toes are physiologically flexors, while the corresponding plantar flexors are extensors. In all that follows these important muscles will be grouped according to this nomenclature.

1. Loss of voluntary power varies from slight weakness of one group of muscles to complete paralysis of both limbs, and depends on the degree of damage to the pyramidal tracts. It usually begins in the distal segments of the limb, and is greater in the flexors than in the extensors.

2. The tone in all the muscles increases early, and is greatest in the extensors. Hence an early symptom is general stiffness of the limbs, especially a difficulty in flexing them. If the limbs are handled passively, the resistance to flexion is found to be greater than to extension. As power diminishes spasticity increases, until at length the limbs are held constantly in an attitude of complete extension. This combination of weakness and spasticity with extended lower limbs is known as “paraplegia in extension.”

3. Exaggeration of the tendon reflexes is a constant early sign. The abdominal reflexes below the level of the lesion and the cremasteric reflexes are lost early. The normal plantar reflex is also lost, and is replaced by a different kind of reflex—Babinski's sign, the “extensor” plantar response.

As the damage to the cord increases, and when certain extra-pyramidal motor tracts are affected, the extensor muscles gradually lose their tone, for which connections with the brain-stem through these extra-pyramidal tracts are essential, while the tone in the flexor muscles, which depends on a reflex arc which is purely spinal, is retained. The result is that the knee- and ankle-jerks, which indicate tone in extensor muscles, are lost while the reflexes from flexor muscles (hamstring-jerks) persist. At the same time, in some cases, the limbs are gradually drawn up by the unopposed action of the flexors. This combination of weakness and spasticity with flexed lower limbs is known as “paraplegia in flexion.” At first the flexed position is occasional—flexor spasms—later it becomes constant, but is still due entirely to excess of tone in the flexors. Finally, contractures occur in the muscles, and the deformity becomes permanent. In many cases of compression the stage of paraplegia in extension gradually merges into one of complete flaccidity of all the muscles, without the occurrence of paraplegia in flexion, and all the tendon reflexes are lost.

4. While the limbs are still rigid in extension, the commonest involuntary movement is a spontaneous clonus of the extensor muscles, in which the whole limb trembles as it does when ankle clonus is elicited in a case with marked spasticity. In the later stages, where the extensor muscles are

beginning to lose their tone, a new kind of movement appears, in which the limbs are drawn up suddenly from time to time by an involuntary contraction of the flexor muscles—flexor spasms. Further, by appropriate stimulation many reflex movements can be produced in the paralysed limbs. The most important of these is the “flexion reflex of the lower limb.” It is elicited most easily by stimulating the outer border of the sole by firm pressure or a pin-prick, and in its complete form consists in flexion of the hip and knee, dorsiflexion of the foot, and an upward movement—so-called extension but physiological flexion—of the great toe. When the damage to the motor tracts is slight, when the limbs are rigid in extension and the movement of flexion is prevented by the hypertonus of the extensors, or when almost all reflex activity has disappeared, the reflex appears in its minimal form. A part of this minimal response is an “extension” of the great toe. The normal plantar response is obtained from the sole alone. The pathological reflex, of which the “extensor” response is a part, may be obtained not only from the sole, but when well developed by stimulating the skin and deeper structures on any part of the lower limb. In the light of this the nature of many reflexes which have been described as isolated signs of pyramidal tract disease, *e.g.* the “extensor” plantar response, Oppenheim’s and Gordon’s signs, and many others, becomes clear. In all of them a stimulus is applied to some part of the lower limb, and the response is a flexion reflex, whose most obvious component is “extension” of the great toe. It is unfortunate that the term “extensor response” is commonly used to describe a movement which is physiologically one of flexion.

Sensory symptoms.—Sensory loss may appear first in the area supplied by the roots arising from the cord at the level of the lesion, or in parts below. As a rule motor disturbance is severe before any remote sensory loss is found. In some cases, especially of spinal caries, the limbs are completely paralysed before sensation is affected. The reverse condition, severe sensory loss with slight motor disturbance, does not occur in compression. Remote sensory loss appears first in one of two positions. In most cases the soles first become less sensitive, then the legs, and later the thighs. In a smaller number the loss appears first over the lower sacral segments, and extends upwards in segmental progression. When both sides are equally compressed all forms of sensation may suffer equally; but in most cases position and passive movement, temperature, pain and touch are impaired in this order.

If one side of the cord is more affected than the other the signs are those of a modified Brown-Séquard syndrome with the superficial sensory loss greatest in the limb in which most power is retained, and loss of position and passive movement greatest in the weaker limb. Ultimately, whatever the order of loss at the beginning, as the compression increases, sensation of all kinds is diminished or lost in all parts below the lesion. In exceptional cases the skin in the distribution of the lowest sacral segments retains its sensibility when the loss in all other parts below the lesion is severe. Such a distribution of sensory loss suggests a lesion damaging the more mesial fibres of the sensory path. Occasionally the onset of symptoms in extra-medullary compression is rapid, and severe paraplegia develops in a few days. This is seen most often in cases of sarcoma of the mediastinal or retro-peritoneal spaces where the growth, which has infiltrated one or more vertebral bodies, surrounds the dura and produces œdema of the cord. In cases of rapid

onset the limbs are flaccid from the beginning, and the tendon jerks are diminished or lost.

INTRADURAL COMPRESSION.—When the pressure is equal on both sides of the cord, the symptoms are the same as in extradural compression. If one side is affected before the other, as by tumours growing from a nerve root, the symptoms are at first unilateral, and in many cases spasticity and weakness are confined for a long time to the lower limb on the same side as the tumour. Occasionally alterations in subjective sensation (*paræsthesiæ*) in the limb of the opposite side precede motor symptoms by a considerable interval, and form the grounds for the patient's first complaint.

At a later stage the following characteristic syndrome appears :

1. A band of sensory loss, on the side of the tumour in an area corresponding to the distribution of the sensory roots arising from the cord at the level of the lesion, often with root pains in the same area.
2. Weakness and spasticity confined to or greatest in the limb on the same side (pressure on the pyramidal tract).
3. Diminished sensibility to temperature, pain, and touch on the opposite side (pressure on the crossed sensory tracts).
4. Impairment of the sense of position and passive movement in the weaker limb (pressure on uncrossed sensory tracts in the posterior columns).

As the compression increases both limbs become weak, spastic and insensitive, and the symptoms progress as in extradural compression. Examination of the cerebro-spinal fluid often reveals a condition which is practically pathognomonic of compression—the *loculation syndrome*. This consists, in its complete form, in an increase in the amount of albumin with absence of or slight increase in the number of cells, and a yellow colour (*xanthochromia*) in the fluid. The normal amount of albumin is about 0·025 per cent. In compression it is often increased a hundredfold or more, and readings above 1 per cent. are very common. A low cell count and 0·1 per cent. of albumin is very strong evidence of compression, and as the amount increases the diagnosis becomes more certain. *Xanthochromia* is common; but it occurs in other conditions, and its value as a sign is slight. These changes are found in the fluid only below the site of compression.

Diagnosis.—A complete diagnosis establishes—(1) the existence of compression; (2) its situation; (3) its pathological nature.

1. When signs of injury to the cord or nerve roots are found associated with disease of the spine at a compatible level the diagnosis is obvious. When root pains are the only symptom the diagnosis is difficult. They are often falsely interpreted as referred pains, or as indications of disease in the painful part itself. Thus *angina pectoris*, *gall-stones*, *pleurisy*, *renal colic*, *hip-joint disease* and other painful conditions have been diagnosed, and unnecessary operations have been performed. Pain of root distribution should always arouse suspicion, and provoke a careful examination of the spine and of the nervous system.

If the signs are those of spastic paraplegia, spinal syphilis, disseminate sclerosis, syringomyelia and amyotrophic lateral sclerosis must be excluded. *In almost every case this can be done in one stroke by examination of the cerebro-spinal fluid.* Patients with removable spinal tumours are still allowed to develop incurable paralysis, because this examination is not made. Such

an omission in a case of paraplegia of doubtful origin amounts to neglect. The loculation syndrome in the fluid is almost pathognomonic. It is never absent in chronic cases, and is never found in any of the focal or system diseases, for which compression might be mistaken.

Spinal syphilis is detected by examination of the blood and cerebro-spinal fluid. Valuable time may be lost, however, or an irretrievable error made, when the blood of a patient with a removable tumour happens to react positively to Wassermann's test. In a series of cases operated upon by Sargent at the National Hospital, the reaction was positive in four patients from whom a non-syphilitic tumour was removed.

Disseminate sclerosis may present the picture of progressive spastic paraplegia with considerable sensory loss, and confusion between it and compression by slowly growing tumours is common, each disease being mistaken for the other. The more serious error is to mistake the curable for the incurable disease. It is advisable to feel dissatisfied with the diagnosis of disseminate sclerosis, so long as the symptoms are purely spinal, and to re-examine the patient at intervals in the hope of finding evidence of a simple tumour. The transient nature of the early symptoms and the presence of signs of cranial nerve troubles serve to distinguish disseminate sclerosis in most cases. Slight nystagmus must not be accepted as decisive evidence against tumour, as it is common in compression, especially of the cervical region.

Amyotrophic lateral sclerosis simulates compression in the cervical region, in that wasting in the muscles of the hands and arms is associated with signs of spastic paraplegia in the lower limbs; but is distinguished by exaggeration of the tendon reflexes in the wasted arms, by fibrillary tremors in the muscles, and by the absence of objective sensory disturbances.

Syringomyelia is easily recognised by the characteristic sensory changes. Dissociation of sensation to the degree which is common in this disease is never seen in extra-medullary lesions.

2. SEGMENTAL DIAGNOSIS.—As the motor sensory and reflex functions of each segment of the cord are known, the level of the lesion can be deduced by noting the highest point at which these functions are impaired.

Motor localisation.—Each segment of the cord contains nuclei for several muscles, and most muscles receive nerve fibres from more than one root; but as each muscle seems to have one main root of supply, the weakness, wasting and loss of tone vary in distribution with the segment affected. The muscles which suffer most when the corresponding segment is damaged are named hereunder:

- C₄. Supraspinatus, infraspinatus. C₅. Biceps, deltoid, brachialis anticus, supinator longus. C₆. Pronators of forearm. C₇. Triceps, extensors of wrist and fingers. C₈. Flexors of wrist and fingers. D₁. Small muscles of the hand. D₂₋₁₀. Intercostal muscles. D₇₋₁₀. Muscles of abdominal wall. D₁₂-L₁. Ilio-psoas (mainly L₅). L₂. Adductors of thigh. L₄. Abductors of thigh, extensors of knee. L₅. Hamstrings. S₁. Glutei—calf muscles. S₂. Anterior tibial muscles—peronei—small muscles of foot.

Wasting of the muscles in an intercostal space is a valuable guide, as the muscles of each space are innervated from one segment alone. If the lesion is at the level of the ninth dorsal segment the rectus abdominis is paralysed below a point about an inch above the umbilicus. In such a case, when an

attempt is made to rise from the lying to the sitting position, the upper part contracts and the umbilicus is drawn upwards (excursion of the umbilicus). If the lesion is at the twelfth dorsal segment the entire rectus contracts, but the iliac regions bulge, owing to paralysis of the lower part of the oblique muscles.

Localisation by changes in the reflexes.—Above the lesion the reflexes are normal, at its level they are diminished or lost, below it the skin reflexes are diminished or lost, and the tendon reflexes are exaggerated. The segments on which important reflexes depend are :

*C*₆. Biceps and supinator-jerks. *C*₇. Pronator-jerks. *C*₇. Triceps-jerks. *D*₇₋₁₂. Abdominal reflexes. *L*₂. Cremaster reflexes. *L*₄. Knee-jerks. *S*₁. Ankle-jerks. *S*₂. Plantar reflexes.

Sensory localisation.—The sensory areas supplied by each segment of the cord are shown in the accompanying diagram (p. 1598). Root pains in the distribution of one or more of these areas form a sure guide to the affected segment. When they are absent, the level of the lesion is determined by ascertaining the highest point at which sensation is impaired. Very often when the two sides of the cord are compressed unequally the anæsthesia is confined to one side, or extends higher on one side than on the other. In these cases, when the segmental diagnosis is made from the sensory signs alone, the lesion, a tumour for example, is found several segments higher than the point indicated by the signs. The uppermost limit of sensory loss in these circumstances does not correspond with posterior roots injured by the tumour—if it did, the localisation would be accurate—but is a result of interruption of the sensory paths in the cord, and the discrepancy in the signs is due to the oblique course taken by the sensory fibres in crossing the cord. In the mid-dorsal region the decussation for pain and temperature is complete one segment above the point of entry of the root conveying these impressions to the cord, that for touch in two segments. As the cord is ascended, crossing takes place more slowly, until in the upper cervical region impulses which enter together in one root ascend on the same side of the cord for five or six segments before all of them reach the opposite side. At all levels pain crosses soonest, then cold, then heat, and touch slowest of all.

It follows that in unilateral lesions the upper level of the anæsthesia on the opposite side of the body, caused by injury to sensory paths in the cord, is below the segmental level of the injury. Also that the level is higher for one form than another. The fibres which cross slowly escape by ascending beyond the lesion on the uninjured side before they cross, while those which cross quickly are caught after crossing. Hence the level of sensory loss is highest for pain and lowest for touch, with temperature intermediate. Occasionally the tumour is found below the level predicted. In these cases the functions of the segments above the lesion are impaired by œdema.

Surface anatomy.—If the cord is to be exposed at the level of the affected segments their relation to the spinous processes of the vertebræ must be known. This is obtained as follows: In the cervical region to the number of the spine add 1—the fifth cervical spine lies over the sixth cervical segment; to the number of the upper five dorsal spines add 2—the fourth dorsal spine lies over the sixth dorsal segment; down to the tenth dorsal spine add 3—the tenth dorsal spine covers the first lumbar segment. The eleventh

dorsal spine corresponds to the third lumbar segment, and the twelfth to the first sacral. The cord terminates just above the level of the first lumbar spine.

Intrathecal injection of lipiodol.—The upper level of a lesion which narrows

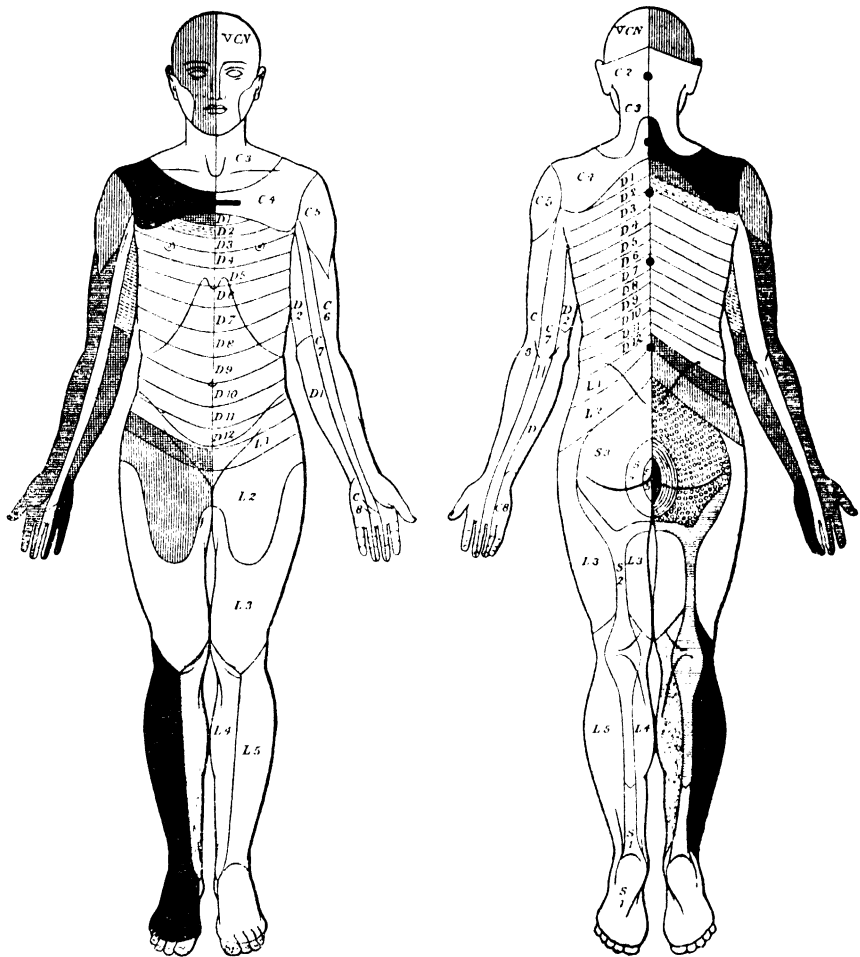

FIG. 115.—Diagram of cutaneous areas of posterior nerve roots (after Collier and Purves Stewart).

or obliterates the lumen of the spinal canal can be ascertained by injecting lipiodol through the occipito-atlantoid ligament into the subarachnoid space. The lipiodol falls rapidly to the point of constriction, where it is arrested and can be seen clearly by X-rays. If there is no constriction it falls to the dural cul-de-sac, where it remains indefinitely and does no harm. This

procedure is of great practical value when the existence of a compressive lesion or its exact site is in doubt.

3. DIAGNOSIS OF THE CAUSE OF COMPRESSION.—When spastic paraplegia develops in a patient who is known to suffer from *spinal caries*, the cause is obvious; but when it precedes the appearance of signs of bone disease the diagnosis is difficult. In all cases of compression the spine must be examined repeatedly for deformity, tenderness and limitation of movement. If tenderness is found constantly in the same place, and the nervous symptoms are compatible with disease of the underlying segments, disease of the bones is almost certain. In young persons disease of the spine is usually *caries* and in adults *caries* is also the commonest cause; but tumours of the spine and aneurysm must be excluded. Severe root pains are rare in *caries* but are the rule in vertebral new-growths. An aneurysm would present other signs. An X-ray picture will usually demonstrate the presence and nature of the bone disease.

Vertebral tumours.—When root pains occur in a patient with malignant disease, or from whom a malignant growth has been removed, the diagnosis is clear. Mistakes are easily made when pains are the first symptom, as their root origin is not recognised. Diminished sensibility in the painful area indicates the nature of the pain, and this directs attention to the spine, where tenderness or deformity is discovered. As most vertebral tumours are secondary, the next step is to examine the parts where carcinoma is common, remembering that a small primary growth, e.g. in the breast, thyroid or prostate, may give rise to widespread metastases in the bones. In the absence of a history or signs of new-growth in other parts, the diagnosis is founded on the combination of local tenderness or deformity and rigidity of the spine with root or cord symptoms. The severity of the root pains, and their great aggravation by movement, are characteristic.

Meningeal tumours.—Severe pain of root distribution is present in many cases, and when this is followed after some time by spastic paralysis of slow onset and steady uninterrupted progress, affecting first one leg and then the other, the combination and especially the course of the symptoms are almost pathognomonic. In *caries* the root pains are rarely severe, signs of bone disease are rarely absent, the paralysis is usually bilateral from the beginning, and is severe before any sensory loss is found. The distinction from vertebral new-growth may be impossible when the latter occurs without bone symptoms or X-ray signs. Practically the diagnosis between meningeal and intra-medullary tumours is impossible. If the signs and symptoms in any case are those of compression, and an approximate indication of the level of the lesion can be given to guide the surgeon, then, if other obvious causes such as *caries*, aneurysm and vertebral tumour have been excluded, an operation must be performed. Until the lesion can be seen the diagnosis is in doubt.

Course and Prognosis.—*Spinal caries.*—The course of the bone disease does not always run parallel with the paralysis, and either may alter in severity independently; but if the *caries* undergoes cure the paralysis usually diminishes. Considering the severity of the paralysis, the prognosis is favourable and astonishing recoveries occur. The outlook is best in young people with disease in the dorsal region. Many recover completely, but more often, especially in adults, recovery, though considerable, is partial. So long as the lower limbs remain spastic in the extended position with exaggerated

tendon reflexes the prognosis for complete recovery of power is good; but if the limbs become flexed, if they become flaccid, if the knee- and ankle-jerks are lost, if sensory loss is severe, or if there is wasting in the limbs following damage to lower motor neurons, the outlook is very bad. Many patients live for years with severe paralysis; but life is constantly endangered by sepsis from bed-sores, ascending infections of the urinary tract, chest complications, and tuberculous disease in other parts.

Vertebral tumours.—When sarcoma or carcinoma spreads to the vertebræ from surrounding parts the duration of the disease is measured in weeks or months, and death is due to the primary condition. In primary sarcoma, and in some cases of carcinoma of the vertebræ, life may be prolonged for a year or two, and death is due rather to complications of the cord disease—bedsores, cystitis, etc.

The course of *tumours of the meninges* is often extremely slow. Root symptoms may precede paralysis by months or even years, and the weakness may increase gradually for several years before walking becomes impossible. Malignant growths are fatal, and simple growths equally so, if not removed. Most patients with simple tumours come to operation during the second year after the onset of the first symptom. The mortality after operation for the removal of simple tumours is very low in skilled hands. The prognosis for recovery of power depends in part on the duration of the weakness in the lower limbs. Complete recovery may be expected, if it has not lasted more than a year. When the paralysis is of longer duration recovery, though gratifying, is rarely complete. Nevertheless, full return of power has been seen after 3 years of severe paralysis.

Treatment.—*Spinal caries.*—This is to be directed to curing the bone disease in the hope that cure of the paralysis will follow. Complete rest on the back and fixation of the spine for many months is the routine treatment. The general condition of the patient is to be improved by fresh air, a liberal diet and cod-liver-oil, iron and arsenic, and great care is to be taken to prevent bedsores, cystitis and deformities of the limbs. For adults, especially if they are bread-winners, a more rapid cure is desirable. This is provided by surgery in Albee's operation, or a modification thereof, in which a bone graft from the tibia is wired into a cleft made in the spines of the affected region. In this way fixation is effected, further deformity is prevented, and the time lost is reduced from a year or more to a few months. Adults sometimes recover after a short rest in bed, if a suitable jacket is worn to immobilise the spine.

Operation must be considered—(1) when a sudden increase of deformity or severe root pains and great increase of paralysis come on together, and suggest pressure by displaced bone; (2) when an abscess forms; (3) when paralysis persists long after the bone disease is cured, or when in an adult there is no improvement after 6 months' rest; (4) when life is endangered by respiratory paralysis.

Vertebral tumours.—In slowly growing primary growths of the vertebræ laminectomy is indicated to relieve pressure, or to prevent pain by cutting sensory roots or dividing the antero-lateral columns of the cord. The operation is merely palliative, but is often followed by considerable temporary recovery.

Meningeal tumours.—If the symptoms suggest an intraspinal tumour,

and a segmental diagnosis has been made, an exploratory laminectomy should be done in the hope of finding a removable tumour.

COMPRESSION OF RAPID ONSET

Ætiology.—The commonest causes of rapid compression are fracture or dislocation of the spine.

Dislocations occur most often between the atlas and axis, or between the fifth and sixth cervical vertebræ. They are sometimes incomplete, and thus may cause compression of slow onset. More often they are complete, and the cord is compressed between the laminae of the dislocated vertebra, which is displaced forwards, and the body of the underlying vertebra. Fractures are commonest in the lower dorsal and upper lumbar regions, and follow most often a fall from a height on to the feet or buttocks. They also occur apparently spontaneously in spinal caries and in vertebral tumours. A blow on the back may fracture the vertebral arches, and cause compression of the cord. The degree of damage to the cord varies greatly. In most cases it is very severe, the cord being completely divided or the damaged part transformed into a soft hæmorrhagic pulp.

Symptoms.—Sudden severe compression causes flaccid paralysis, sensory loss and loss of all reflexes in parts below the lesion. At first there is retention of urine, which is followed later by incontinence. Bedsores often develop with extreme rapidity.

Prognosis.—The prognosis is always extremely grave in severe cases, death resulting in high cervical lesions from paralysis of all the muscles of respiration, in lesions at lower levels from sepsis following bedsores, or from infection of the urinary tract.

Treatment.—When the signs are those of complete division of the cord, treatment by operation is directly contra-indicated. If some voluntary power is retained, or if sensory loss is not absolute, operation may be considered, especially if the compression is caused by fracture of the vertebral arches. The cord should be exposed in every case where the level of the fracture points to injury of the cauda equina. These roots being peripheral nerves have a chance of regenerating, and this may be enhanced by freeing them from compression by displaced fragments of bone. With skilled nursing, patients with complete division of the cord may survive and live for many years. Prevention of bed-sores, and of bladder infection is of first importance.

SYRINGOMYELIA

Definition.—Syringomyelia is a very chronic and irregularly progressive disease of the spinal cord and brain stem, dependent upon a peculiar lesion of the grey matter, glial increase and the formation of irregular cavities being the most conspicuous features of this lesion. Clinically, the malady is characterised by a deep loss of sensibility to pain and to temperature, other forms of sensibility remaining relatively unaltered, and by muscular atrophy and weakness of varying distribution in the upper extremities, and further by spastic weakness of the lower extremities, owing to involvement of the pyramidal tracts at the level of the lesion.

Ætiology.—Both sexes may be affected, and males are more prone to suffer than females. Heredity plays no part in its causation. Age is most important, in that this disease appears either to be congenitally installed, or to commence during the period of growth. It has been diagnosed with accuracy as early as the sixth year of childhood, and rarely if ever do the symptoms commence later than the age of 30 years.

Pathology.—The primary lesions of syringomyelia are always found in that region of the spinal cord which was originally occupied by the central canal, or in close connection with the ventricular system of the brain stem; and it is certain, therefore, that syringomyelia is referable to a pathological process affecting the central canal and its surrounding glia, and that this pathological process, in many cases at least, is installed before the completion of the development of the central canal of the nervous system. Two essential lesions and four other commonly occurring lesions make up the morbid process of this disease :

Essential lesions.—(1) Cavitation of the posterior part of the grey matter ; (2) gliosis, with liquefactive degeneration of the abundant glia — *other lesions commonly but not invariably present* ; (3) degeneration of lower motor and vasomotor neurons ; (4) degeneration of lower sensory neurons ; (5) distension of cavities producing pressure effects ; (6) secondary ascending and descending degenerations.

The seat of commencement of the disease is invariably in the dorsal grey matter of the lower half of the brain stem and upper half of the spinal cord, and most commonly of all, in the lower three cervical and upper three dorsal segments. The cavitation occurs primarily always in that part of the grey matter which held the original central canal, namely, the region of the posterior commissure, posterior median septum and posterior horns. The cavities are roughly fusiform in shape, with the long axis in the length of the cord, and may be short or very long, single, multiple, or branched. When multiple, there is a tendency for the cavities to break into one another sooner or later. The contents of the cavities is a colourless or slightly yellow fluid, containing no cellular elements, and little or no albumin. Distension of the cavities may reach so great a degree as to cause the spinal cord to fill the spinal canal and press upon the bones, and in rare cases may cause such evascularisation as to produce complete transverse softening of the cord. It is the cause of extension of the cavitation, especially in the direction of length of the cord.

The gliosis consists of a thick layer of neuroglial tissue, which everywhere surrounds the cavities, and which at their upper and lower limits extends some distance farther than the cavity, as a solid mass. Farther than this, in the regions affected, solid masses of glial tissue of considerable size may be seen, and these appear from their position to have developed from the collections of undifferentiated neuroglia, which, normally, occupy the position of the obliterated lateral horns of the primitive central canal. In the medulla and pons, such masses may be found anywhere in the reticular formation, and are especially frequent in the lateral region of the medulla, mesial to the restiform body and ascending root of the trigeminal nerve, where the vagus-accessory nucleus and the main afferent paths for pain and temperature sensibility are situated.

Degeneration of the lower motor neurons occurs in at least half the cases.

It is most marked in the cervical and upper dorsal regions of the cord, and may be very local or extensive. It is commonly explained as caused by the extension of the gliosis and cavitation into the anterior horns of the grey matter, and by the distension of the cavities exerting pressure upon these regions, and causing atrophy of the cells. To the pressure exerted by such distended cavities, are also attributed the ascending and descending degenerations which are commonly found in the pyramidal tracts below the level of the lesion, and in the posterior columns above.

Tumour formation is not uncommon in cases of syringomyelia. Massive growth may be found in the pons and in the spinal cord.

Symptoms.—*Disturbances of sensibility.*—By far the most constant and characteristic feature of syringomyelia is a sensory loss of a peculiar kind which was named by Charcot “the dissociated sensory loss.” This is a loss of sensibility to painful impressions and to thermal stimuli, while sensibility to touch, to vibration, to position, to passive movement and to the appreciation of location upon the skin, remain relatively or entirely intact. In other words, those forms of sensibility which travel by a path crossing in the posterior grey commissure of the spinal cord are lost, because the lesion of syringomyelia destroys especially the region of the posterior commissure, while those forms of sensibility which travel by paths which are uncrossed in the spinal cord and do not traverse the region especially affected by syringomyelia, but are conducted by the posterior columns, are not affected. Further, the lateral region of the dorsal reticular formation of the medulla, mesial to the restiform body and ascending root of the fifth nerve, and a little ventral to these structures, is especially prone to the lesion of syringomyelia, and it is this region which contains the whole path for pain and temperature sensibility from the opposite half of the body, and a lesion in this situation will produce hemianalgesia and hemithermanæsthesia, while the paths for other forms of sensibility, situated mesially on either side of the raphe of the medulla, escape. Again, the lesion excavating the ventral horn in any part of the cervical region may extend so as to interrupt the spinothalamic tract which lies immediately dorso-lateral to the ventral horn, and so cause loss of pain and temperature sense on the opposite side everywhere below the level of the lesion.

The destruction of the posterior commissure in the lower cervical and upper dorsal regions produces the dissociated sensory loss symmetrically over the thorax, upper extremities, neck and face, the distribution varying with the extent of the lesion. The sensory loss over the face is explained in that the sensory root of the trigeminal nerve has its ending in the upper three segments of the cervical spinal cord, and the pain and temperature sensibility of the face is interfered with, if the posterior grey commissure in the region of these segments is damaged. Only rarely does the symmetrical sensory loss extend below the thorax, for the reason that the spinal lesion does not often extend below the mid-dorsal region. The sensory loss will vary in depth, extent and symmetry of distribution according to the completeness, extent and symmetry of the lesion. Thus, in early and slight cases, the sensory disturbance may not amount to more than a relative loss of pain and temperature confined to the hands and ulnar borders of the forearms, while in an advanced case there is usually complete inability to appreciate painful and thermal stimuli over an area which would be covered

by a sleeved jacket, and this area often extends over the neck and the face. Combinations of the "sleeved jacket" sensory loss with hemianalgesia and hemithermanæsthesia often occur in cases where both the spinal lesion and the medullary lesion are present. The dissociated sensory loss makes its advent insidiously, and is often unnoticed by the patient and discovered for the first time on medical examination. Or, it may appeal to the patient, who on bathing finds that he appreciates heat and cold upon some parts of the skin and not on others. Not infrequently he finds that he injures himself or burns himself without noticing it at the time.

Subjective sensibility is not often affected, and for the most syringomyelia may be described as a painless disease; but there are very notable exceptions. Sensations of heat and cold, dull fixed pains, lasting neuralgic pains, and lightning pains in no way differing from those of tabes, may occur. These pains are confined to the regions which are the seat of the other symptoms. Especially important in this connection are those cases in which the distension of the cervical spinal cord is so great as to cause that structure to press upon the bones of the spinal canal. Here constant and often intolerable aching pain in the neck, upper extremities and thorax may result, with rigidity of the neck, and this may render life so insupportable as to necessitate surgical interference for the relief of the pressure.

Muscular atrophy.—This common clinical feature of syringomyelia is met with in considerably more than half the cases. It is wrongly described as a "progressive" muscular atrophy, for it is dependent upon the local lesions of the grey matter, and often does not progress beyond a certain degree, which may be slight. As may be gathered from the nature of the lesions, though usually bilateral, it is often not symmetrical, and may be entirely confined to one side. The intrinsic muscles of the hands and the muscles of the ulnar side of the forearms are first and most affected in the ordinary run of cases. The atrophy is often here confined, but it may extend up the arm; but it is unusual for the whole upper limb to be affected. Sometimes the shoulder muscles are first affected, and again the scapulo-thoracic and humero-thoracic muscles may be early involved. The upper intercostals, and that section of the muscles which support the spine, supplied from the upper six dorsal segments suffer, but the scalenes seem generally to escape. The muscular atrophy is strictly limited, and is apt to become complete in the muscles affected. The lesions of the medulla may involve the motor nuclei of the cranial nerves. Atrophic paralysis of the muscles supplied by the vago-accessory nerve is far from uncommon, and the discovery of this paralysis in a young subject should always arouse suspicions of the presence of syringomyelia. The paralysis is unilateral and involves palate, pharynx and all the muscles of the larynx upon the affected side. Similarly but in much rarer cases, atrophic paralysis of the face, of the trigeminal muscles, of the sternomastoid and trapezius or of the hypoglossal muscles may occur from a unilateral involvement of the corresponding motor nuclei. Fibrillation in the affected muscles is said by most writers to be of common occurrence. It has been conspicuous by its absence in most of the large number of cases which have come under our observation. One would expect it to be confined in syringomyelia to such times as the muscular atrophy is progressing.

Contractures resulting from the muscular atrophy are commonly seen in the hands, and the deformity resulting tends towards the "griffin's paw"

type, but hardly reaches the degree seen in ulnar nerve paralysis, and is often much modified by trophic and vasomotor changes, and by the results of injuries and whitlows.

The lower extremities escape so far as atrophy of muscles is concerned. Spinal curvature is present in many cases. It consists essentially in a kyphosis or kypho-scoliosis of the upper dorsal region, with a compensatory lordosis and lateral curve in the lumbar region. The upper convexity is to the left from the major use of the right hand. It is dependent upon paralysis of the trunk muscles, from involvement of the anterior horns in the upper dorsal region, and, in addition, dystrophic changes in the bones may be factors in its production. It is more marked the earlier it commences during the period of growth, and where heavy manual occupation has been followed.

Two other forms of paralysis may be met with in the upper extremity, either alone or combined with the atrophic palsy. The one is a spastic paralysis, usually incomplete and often slight, due to the involvement of the crossed pyramidal tract in the lateral column of the cervical spinal cord, anywhere above the fifth cervical segment. The other is a peculiar and usually complete flaccid palsy of the hand without muscular atrophy, and presumably this is the result of a local lesion in the region of Clarke's column and the posterior horn, which, on the one hand, destroys the terminations of the pyramidal tract in Clarke's column, thereby producing the local paralysis, and, on the other, cuts the reflex arc from the posterior roots to the anterior horns, thereby rendering the paralysis flaccid.

Trophic and vasomotor disturbances.—Thickening of the bones or a condition of osteoporosis and brittleness may be met with. More often Charcot's arthropathy occurs. It differs in no way from the similar condition in tabes dorsalis, and is confined to the joints of the analgesic region, and affects the joints of the lower extremity only when there is a hemianalgesia from a lesion of the spinothalamic tract either in the cord or in the medulla. In syringomyelia Charcot's joints are seen chiefly in workmen who are engaged in occupations which constantly expose the analgesic joints to jarring and bruising.

The most characteristic of the trophic changes consists in thickening of the subcutaneous tissue and of the skin itself, which is seen in the hands. The fingers become thick and swollen and lose their natural outline, the tips become blunted, and the knuckle-folds thick and coarse, and some vasomotor paralysis renders them unduly red, or even blue. They have been termed "sausage-like" fingers, and often stand out in contrast to the wasting of the intrinsic muscles of the hand. A similar condition affecting the whole hand is common, and was termed by Charcot the "fleshy hand" or "main succulente." The analgesic condition of the hands and the thermanæsthesia present expose them unduly to injuries and, since these injuries are likely to be unnoticed or disregarded, septic infection arises easily, and the results of injuries, burns and whitlows are frequently seen, giving rise to further deformity from scars, loss of the terminal phalanges, from whitlows and contractures, and from sepsis extending to the tendons.

The lower extremities usually present a slight spasticity, with the signs of involvement of the crossed pyramidal tracts. This does not often produce much disability in the use of the lower limbs. In cases, however, where the lesions involve the lateral regions of the cord, either by direct extension or by

the pressure of distended cavities, severe spastic paraplegia may result. And again, in very rare cases, such pressure may lead to total evascularisation and total transverse lesion of the spinal cord with the appearance of a complete flaccid paraplegia with incontinence, total sensory loss and absent deep reflexes.

Sphincter trouble is usually absent, or slight and occasional; but in cases where paraplegia is severe any degree may occur.

The skin reflexes of the trunk are diminished or absent, and the plantar reflexes are of the extensor type, according to the degree of pyramidal involvement. Some degree of pes cavus is often present. The knee-jerks and ankle-jerks are increased, and foot-clonus, etc., is present.

Considering that the efferent neurons of the cervical sympathetic system have their origin in the brain stem, and their exit from the spinal cord in the lower cervical and upper dorsal segments, thus traversing the whole of the region usually affected by the lesion of syringomyelia, the frequency with which paralysis of the cervical sympathetic occurs is easily understood. It may be complete or incomplete, unilateral or bilateral, and is recognised by smallness of the pupil, narrowing of the palpebral aperture (sympathetic ptosis), enophthalmos, and a peculiar flatness of expression on the side of the face affected, with decrease or loss of sweating. These signs are much more obvious when unilateral than when bilateral, for, in the absence of the contrast which a normal side of the face gives, they are often overlooked when bilateral.

Papilloedema has been recorded in several cases. It may be due to the occasional massive tumour formation within the skull case, to which reference has already been made; but more often it is the result of the enlargement of the cervical region of the spinal cord, which may tightly fill the theca and completely obstruct the spinal outflow of the cerebro-spinal fluid, and so give rise to a relative hydrocephalus. Ophthalmoplegia is very rare, but it may occur, since the syringomyelia lesion may be found as high as the region of the third nucleus. Nystagmus is an almost constant feature of syringomyelia, as it is also of most lesions of the cervical spinal cord. It may be due to pontine lesions of the brain stem, which interfere with the cerebellar connections, or to lesions of the cervical cord which involve cerebellar afferents, and which interfere with the physiological connections between eye movements and neck movements.

MORVAN'S DISEASE.—This variety of syringomyelia is so peculiar in its clinical aspect as to need especial description. In addition to the lesion of the spinal cord characteristic of syringomyelia, there are intense changes in the periphery of the nerve trunks of the limbs. Instead of the usual loss of pain and temperature sensibility, distributed in jacket form upon the upper limbs and trunk, there is absolute loss of all forms of sensibility in the hands, wrist high, and in many cases also in the feet, ankle high. Progressive atrophy of the intrinsic muscles of the hands and feet occurs. Severe vasomotor paralysis brings about permanent cyanosis of the hands and feet, with much thickening of the skin and subcutaneous tissues, to which is added the effects of injury and septic processes in insentient regions, in the form of whitlows, necrosis and loss of digits. Gowers states that the affection of the feet is rare, but in three cases which we have had under our care, the hands and feet were equally affected; the loss to all forms of sensibility was sharply limited at the wrist and ankle; while the presence of abnormalities

of the pupils and of the palpebral apertures, as well as spinal curvature, were certain indications of the lesion in the cervical cord. These three cases had been diagnosed as Raynaud's disease. Another peculiarity of this malady is that the extremities are exceedingly painful in the early stages and until the sensory loss becomes deep. Morvan's disease resembles Raynaud's, disease in the cyanosis and tendency to necrosis of the fingers and toes, but it is easily distinguished by the complete absence of intermittent vascular spasm and by the peculiar loss of sensibility. Anæsthetic leprosy may be distinguished from Morvan's disease by the characteristic skin lesions in other parts of the body, by the palpable thickening of the nerve trunks, and by the less definitely limited areas of sensory loss. Every transition between typical syringomyelia and Morvan's disease has been described.

Course and Duration.—The malady, commencing insidiously, progresses very slowly, and often ceases to progress for periods which may amount to many years. The tendency to the destruction of life is not great; but when rapid extension of the physical signs, and especially of paralysis and muscular atrophy of the upper extremities and respiratory muscles, occurs, the end is likely to come quickly. Signs of great distension of the cavities, such as pain and rigidity of the neck, and also severe and increasing paraplegia, with sensory loss of all forms of sensibility below the level of the lesion, point to a rapidly fatal termination.

It is not unusual to meet with well-marked cases in which the signs develop and increase during late childhood and early adult life, and then remain more or less in a stationary condition, allowing an occupation to be followed until well after middle life has been reached; but with the advent of the degenerative period of life, from the age of 45 years onwards, there is always a slow increase of the disability which puts an end to useful capacity. Many of the cases become incapacitated in early life, after which the disease becomes arrested, and the patients live on for many years, sometimes in a bedridden condition. Few reach the age of 60 years. Rapid extension of the physical signs leads to death from involvement of respiratory muscles. Otherwise the patients succumb to intercurrent disease. Sudden and unexpected death sometimes occurs, and it is especially to be remembered that this is likely to occur after the administration of anæsthetics, and as a result of surgical procedures. In three patients under our care, in whom laminectomy and incision of the distended cavity were performed, two survived and were much relieved, while the third, after he had apparently borne the operation well, died suddenly and unexpectedly on the third day. Another patient, who underwent operation for a surgical condition unconnected with the syringomyelia, and not of a serious nature, died suddenly and quite unexpectedly after recovering from the anæsthetic.

Diagnosis.—Syringomyelia has to be differentiated, in its early stages, from those diseases which cause slowly progressive muscular atrophy in the upper extremities, and, in its later stages, from other lesions of the central region of the spinal cord. Those cases in which the lesions are chiefly in the ponto-medullary region must be distinguished from other slowly oncoming lesions of the brain stem.

The age of onset, during the later years of childhood and the earlier years of adult life, is important, and during this period slowly developing paralysis, with or without muscular atrophy and with sensory loss, should always

suggest the possibility of syringomyelia. Other causes, which may produce this symptom group, and which may be confused with syringomyelia, are local lesions of the peripheral nerves, local lesions of the brachial plexus, and, especially, the lesion produced by the presence of cervical ribs, root lesions, lesions of the central grey matter of the spinal cord, especially central tumours of the spinal cord, hæmatomyelia, and lastly certain general diseases of the nervous system, progressive muscular atrophy, peroneal atrophy and myotonia atrophica. That the sensory changes of syringomyelia of peculiar nature are usually the first signs of that disease is important; but unfortunately is not without many exceptions, both as to the nature of the sensory changes and as to their time of appearance.

Local lesions of the peripheral nerves produce signs which are confined to the distribution of the nerve involved; the sensory loss is to all forms of sensibility, and the condition is commonly unilateral. In syringomyelia, however, the lesion in the early stages may be confined to one side of the cord, and to one posterior horn so far as the production of sensory loss is concerned, and the muscular atrophy may be so narrowly confined to the distribution of the ulnar nerve as to cause close resemblance between the two conditions. Any sensory loss over the trunk, or signs outside the distribution of the peripheral nerve, will, if present, clearly divide the two conditions.

Cervical ribs may produce slowly progressive atrophy of muscles, pains and sensory loss, very difficult to distinguish from those resulting from syringomyelia. The diagnosis in these cases is beset with peculiar difficulties, for so frequently do cervical ribs produce no nervous symptoms at all that their presence, when demonstrated, does not argue that they are the cause of the symptoms. Again, cervical ribs are among the commonest of the developmental peculiarities which are so frequently seen in the subjects of syringomyelia. Moreover, it has been proved, by several observers of the French School, that cases regarded as examples of cervical rib paralysis during life have shown the lesions of syringomyelia upon pathological examination, and it has been argued by these observers that many of the cases accepted as cases of cervical rib paralysis, are in reality cases of syringomyelia. And, further, it must be admitted that the course of some of the so-called cervical rib paralyses, and the unsatisfactory results of surgical interference in others, do not contradict this point of view. Slow muscular atrophy and slowly oncoming sensory loss and perhaps pain characterise both syringomyelia and cervical rib paralysis, and the distribution may be unilateral or bilateral in either condition; but it is only when the signs and symptoms are strictly confined to the upper extremities and neck that difficulty arises. The slightest definite physical sign outside of this region at once turns the diagnosis in favour of syringomyelia, and of these signs cervical sympathetic paralysis, sensory loss on the trunk, and alteration of the abdominal and plantar reflexes are most important. A very careful search must be made for any such signs, and the patient observed over a considerable time before a certain diagnosis is made.

Lesions of the nerve roots, either from inflammatory conditions, bone disease, pachymeningitis or neoplasms give rise to more severe pain than does syringomyelia, and the development of the symptoms is much more rapid. Lesions of the central grey matter of the spinal cord may produce a symptom

complex, closely resembling that of syringomyelia. Central tumours of the spinal cord, when of slow growth, are hardly distinguishable, inasmuch as the lesion of syringomyelia is in reality a central tumour of the cord. The majority of central tumours however are of more rapid development, and speedily produce severe paraplegia. The presence of Froin's syndrome (hyperalbuminosis in the cerebrospinal fluid) is much in favour of tumour.

In hæmatomyelia the symptoms and signs are usually identical with those of syringomyelia; but they are of sudden onset, and reach a maximum intensity in a short time, which is rarely longer than a few hours, and may be as short as a few minutes, after which the symptoms tend to lessen from the absorption of the blood extravasation, or at least to remain stationary. Those cases of hæmatomyelia which have been recorded as subsequently progressing, as does syringomyelia, are certainly cases in which hæmorrhage has occurred into the lesion of syringomyelia, which may have been early or symptomless, and has there lighted up a progressivity in the primary pathological lesion.

Progressive muscular atrophy in its early stages may cause considerable difficulty in diagnosis, and this is easily intelligible when it is realised that the muscular atrophy in syringomyelia may in rare cases precede the appearance of any sensory loss or may be well marked when the sensory loss is slight. Further, some cases of progressive muscular atrophy do show sensory loss at an early stage, and especially over the ulnar sides of the hand and forearm. Fibrillation, which is characteristic of this disease, also occurs in syringomyelia, when the atrophy is progressing, and such signs as slight spasticity of the legs and the extensor response in the plantar reflexes are common to both diseases. It must be pointed out also that progressive muscular atrophy is by no means rare at the age when the symptoms of syringomyelia commence. In this connection widely distributed fibrillation is of great importance in indicating a diagnosis of progressive muscular atrophy, particularly if it be seen in muscles not conspicuously wasted. Uncertainty in the diagnosis between these two diseases is soon dispelled by the lapse of time, which either brings undoubted signs of syringomyelia in its train, or a progressive muscular atrophy with conspicuous absence of such signs. In peroneal atrophy the atrophy of the intrinsic hand muscles is always preceded by a more extensive atrophy of the muscles below the knee, which are never atrophied in syringomyelia.

Dystrophia myotonica is distinguished in that the atrophy of hand muscles is associated with conspicuous difficulty in relaxing the grip, and by the weakness and atrophy of the facial muscles, sternomastoid and quadriceps muscles.

Syringomyelia of the brain stem may be distinguished from other lesions of this region by its insidious onset and the special tendency to the involvement of the lateral region of the medulla containing the vago-accessory nucleus and the central pain and temperature path, so giving rise to a unilateral paralysis of palate, pharynx and larynx with hemianalgesia and hemithermanæsthesia on the opposite half of the body. Often some signs of cervical syringomyelia coexist; but the medullary lesion may exist alone, and it cannot be too prominently borne in mind that any very slowly progressive lesion of the brain stem of insidious onset may be of the nature of syringomyelia.

Prognosis.—Recovery never occurs; but arrest of the disease for long periods is frequent. Those disabilities, which are the result of pressure or distension, may abate spontaneously or as the result of treatment, and in arrested cases training may bring about lessening of the disability. Increasing symptoms, especially if the increase be rapid, are always a cause for anxiety, and increasing involvement of the respiratory muscles is the gravest of events.

Treatment.—Both mercury and iodide of potassium appear to have a definite effect in benefiting the disease when the symptoms are progressing, and are the best measures we have in attempting to influence the course of the disease. Mercury should be administered vigorously for periods of 2 months at a time, and preferably by inunction. Iodide of potassium should be given in moderate doses. Application of X-rays to the cervical and upper dorsal regions of the spinal cord has been followed by beneficial results in the way of arrest of the progress of the disease and improvement of symptoms. Where severe cervical pains, rigidity and pain on moving the neck, or rapidly increasing paraplegia point to great distension of the cavities, surgical measures alone afford relief. Laminectomy with incision of the posterior column, and evacuation of the fluid in the cavity, has been performed with conspicuous success and lasting relief of symptoms. The danger of all operations under an anæsthetic, which has been pointed out above, must be taken into consideration, as it is not likely that more than 50 per cent. of the patients would survive. Cervical puncture is perhaps in skilled hands a preferable measure, but it does not ensure the permanent draining of the cavity as does incision into the posterior columns. Pains are to be relieved with the common analgesics. Massage, exercises and training are all likely to make some improvement in the disability in arrested cases.

HÆMATOMYELIA

Hæmorrhage into the substance of the spinal cord may occur in several forms and in widely separate clinical relations. It may occur without recognisable physical signs. It may result as a secondary event following severe damage to the spinal cord either by injury, inflammation, softening or tumour formation, and is here in the relation of an exacerbator of the physical signs due to the original lesion. If the original lesion be a very severe one, even massive hæmorrhage may produce no addition to the clinical aspect, and so remain unsuspected. Primary hæmorrhage into the spinal cord is, however, of not very infrequent occurrence, and cases of this nature constitute hæmatomyelia as a clinical entity.

The experiments of Goldscheider and Flatau have proved that fluids, when slowly injected into any parts of the transverse area of the intact spinal cord (the posterior white columns conspicuously excepted), tend always to seek the grey matter and there to take up a situation of fusiform shape, especially in the regions of the anterior horns locally, and in the regions of the posterior commissure and posterior horn at a distance.

Massive effusions of blood into the spinal cord may be round or oval in shape and nearly as broad as long, and this happens when clotting occurs rapidly after effusion, and when the bleeding takes place into an area of

softening caused by myelitis, thrombosis or pressure. Much more commonly they are fusiform in shape and occupy the planes of the least tissue resistance. Sometimes the blood is found distending a congenital cleft or cavity in the spinal cord, and it seems clear that in many of such cases the bleeding is determined by the presence of such a cleft or cavity.

SMALL HÆMORRHAGES.—These may be found scattered throughout the spinal cord after death from asphyxia, tetanus, phosphorus poisoning, any hæmorrhagic disease, pernicious anæmia, and after many infective processes. They are found chiefly in the white matter, and may be very numerous. In all these conditions such hæmorrhages seem to be terminal events occurring very shortly before death, and are not associated with any definite symptoms.

TRAUMATIC HÆMORRHAGES.—Since bleeding is a sequel of every severe injury, massive hæmorrhages may be found in cases where gunshot and other penetrating wounds, impact lesions from missiles, bruising from the jar of high explosives, or falls and fracture dislocations have injured the spinal cord. They are of pathological rather than of clinical interest.

SECONDARY HÆMORRHAGES.—Bleeding may occur as a secondary process in poliomyelitis, lethargic encephalitis, myelitis, and in softening of the spinal cord from any cause whatever. In this connection it may be met with following the relief of pressure, when a spinal tumour has been removed. Grainger Stewart has recorded two cases in which hæmatomyelia was secondary to the pressure of an extradural tuberculous abscess.

PRIMARY HÆMORRHAGE.—In this group are included those cases where no cause for the bleeding can be discovered, those in which the factors associated with the onset seem trivial, and where any injury received seems inadequate to account for the result. They form a striking and characteristic group to which the clinical entity of hæmatomyelia is in reality restricted.

Ætiology.—Nearly all the cases occur between the ages of puberty and 30 years. The age incidence falls among young adults, when the mobility of the spinal column, the muscular development, and the possibility of spinal clefts, still persistent, are all likely to be factors in the production of hæmatomyelia. The condition may, however, occur in children at any age. The sexes are equally affected. The most careful investigation often fails to reveal any cause whatever for the onset. Not infrequently a comparatively trivial cause seems responsible, such as straining, coughing, lifting a heavy weight, suppression of menses, exposure to cold and diving into water. The raising of the blood-pressure during moments of intense excitement is certainly the cause of the hæmorrhage in some of the cases. The instantaneous onset of the paralysis, which is so striking a feature where a sudden jerk of the neck, as in diving, coughing, etc., may have been the immediate antecedent, is very suggestive that actual bruising of the cord by the sudden strain is responsible for the lightning-like onset of the paralysis, and that the hæmorrhage is a secondary result of such bruising, for it is difficult to conceive that a hæmorrhage could produce a complete abrogation of the functions of the spinal cord in the space of one second, whereas this might easily result from a slight bruise.

Symptoms.—Hæmatomyelia is characterised by sudden onset, usually without any pain, but commonly with a sensation of numbness, "pins and needles," or an electrical sensation in the region affected. The paralysis

may be instantaneous, as from a sudden bruise of the spinal cord, or rapidly *ingravescent*, such as would result from a quickly gathering hæmorrhage, the local segmental signs appearing first and the paraplegic signs subsequently. The clinical aspect is that of a lesion of the central grey matter of the spinal cord. There is local atrophic paralysis of the muscles supplied by the segments involved, from extension of the hæmorrhage into the anterior horn-cell region with involvement of the sympathetic system, vasomotor paralysis, sweating, and, if the lesion is in the cervical region, with cervical sympathetic paralysis in addition. These signs will be unilateral, bilateral or irregular according to the extent of the damage to the anterior grey matter. There is bilateral loss of sensibility to pain and temperature from destruction of the posterior grey commissure in which the path for these forms of sensibility crosses. The vertical extent of such loss upon the body is determined by the vertical extent of the hæmorrhage in the region of the posterior commissure. There is frequently loss of sensibility to pain and temperature on the opposite side of the body below the level of the lesion, when the latter is more extensive upon one side of the cord, from involvement of the crossed path for pain and temperature, lateral to the ventral grey horn. The posterior columns are conspicuously exempt in most cases, and there is consequently neither loss of touch, nor of position or muscle sense. There is sometimes a zone of hyperæsthesia at the upper limit of the sensory loss. On account of the obliquity of the crossing of the paths for pain and temperature in the posterior commissure, the upper limit of the sensory loss is always a few segments below the upper limit of the muscular wasting.

The general distension of the spinal cord by the increasing hæmorrhage, and the resultant œdema, causes a spastic paralysis below the level of the lesion and interference with sphincter control, with the usual loss of abdominal reflexes, briskness of knee- and ankle-jerk and extensor type of plantar reflex. In this early stage of the malady, cystitis and bedsores may give trouble. Death may occur before the bleeding has ceased, from extension of the hæmorrhage as high as the fourth cervical segment, and consequent paralysis of the diaphragm. Such a fatal result is, however, very rare, for it is most unusual for the hæmorrhage to extend as high as the fifth cervical segment. The intercostal muscles are usually paralysed in cervical hæmatomyelia, either from a downward extension of the hæmorrhage, which is very common, or as a part of the paraplegia.

When the bleeding has ceased and absorption of the clot commences, the symptoms gradually clear up. As the distension of the spinal cord lessens, the spastic paraplegia and the sphincter trouble abate, and in the course of time great improvement may occur and even complete recovery, so far as the paraplegic symptoms are concerned. The initial local atrophic paralysis narrows down somewhat as the local effects of the pressure and œdema produced by the hæmorrhage upon the ventral horns pass off, leaving a permanent atrophic paralysis, with vasomotor paralysis and sympathetic paralysis, corresponding with the regions of the ventral horns which have been irrecoverably damaged. The analgesia and thermanæsthesia resulting from the local destruction of the posterior commissure, remain permanently. The similar sensory loss, due to involvement of the crossed tract in the antero-lateral region of the cord, is transient or permanent according as the lesion in that region is destructive or recoverable.

A few of the cases after making considerable improvement progress as do cases of syringomyelia. Here the explanation is either that a hæmorrhage has occurred in the lesion of a previously symptomless syringomyelia, or that the irritation produced by the hæmorrhage is capable of starting a central gliosis of the spinal cord. The cerebro-spinal fluid shows no abnormality during the first few days following the onset. The hæmorrhage seems never to burst into the meninges. Later on the fluid may present a yellow colour (xanthochromia) from the gradual discharge of the blood pigments from the clot.

Diagnosis.—The diagnosis of primary hæmatomyelia rests upon the sudden onset, the rapid development of symptoms which soon come to a standstill, and the physical signs of a central lesion of the spinal cord, namely, local atrophic paralysis of the muscles, loss of pain and temperature sensibility with a conspicuous escape of other forms of sensibility, and, when the lesion is above the lumbo-sacral enlargement, spastic paraplegia from the general pressure exerted by the hæmorrhage upon the structures of the spinal cord.

The distinction has to be made from acute myelitis and acute poliomyelitis. Acute myelitis, though rapid in onset, does not show the sudden development of symptoms seen in hæmatomyelia. Prodromata often precede the onset. This disease is rare in the cervical and lumbar enlargements, where hæmatomyelia is most common. It usually affects the whole transverse area of the cord and, therefore, does not give the peculiar dissociated sensory loss. It is nearly always of syphilitic origin, and the Wassermann reaction in blood and cerebro-spinal fluid is positive, and the latter shows a lymphocytosis. From acute poliomyelitis, hæmatomyelia may be distinguished by the initial febrile symptoms of the former disease and by the absence of sensory loss and by the lymphocytosis in the cerebro-spinal fluid.

Course and Prognosis.—Following the sudden onset and abrupt development of symptoms, the hæmorrhage ceases in the majority of the cases, and with the gradual absorption of the clot the symptoms abate, leaving the patient permanently crippled to a greater or less extent with atrophic paralysis, spastic paralysis and loss of pain and temperature sensibility, the degree of which varies according to the region of the spinal cord which is affected, and according to the amount of permanent destruction of tissue in the affected segments. During the early stages of the disease there may be danger to life in the cervical cases, from interference with the respiratory muscles and later on from cystitis, bed-sores and pulmonary complications.

Treatment.—Absolute rest is all-essential. It has been often urged that the prone position, or a position lying upon the side, supported by pillows or plank covered with a blanket arranged vertically in the bed, and against which the patient rests, should be secured so that the seat of the hæmorrhage may not occupy the dependent part of the trunk. Such a position, however, must not be maintained at the expense of any respiratory embarrassment, nor involve any possibility of the production of bedsores. Measures should be adopted to allay panic, to keep the blood-pressure from temporary elevations, and to check the hæmorrhage. Morphine, calcium lactate and turpentine are the most likely to be of use in this connection. Ergot in full doses and other vaso-constrictors have been advocated, but it is not certain whether

the increased blood-pressure produced by these drugs may not more than counteract any local vaso-constrictor effect that they may have. Great care must be taken from the first that no distension of the bladder shall occur, for this is the primary cause of cystitis. If cystitis has set in, it is essential to resort to suprapubic drainage at once. The most scrupulous attention must be paid to the skin in the way of cleanliness, hardening and avoidance of pressure, lest bedsores should develop. If lumbar puncture is requisite for diagnosis, a minimal amount only of fluid should be drawn off, and this should be done slowly. Subsequently, the administration of mercury and of iodide of potassium may aid the absorption of the clot. Belladonna in moderate doses is always helpful in aiding the return of sphincter control. Ultimately massage, passive movements, exercises and the application of supporting apparatus are to be employed, as in all other cases of spinal paralysis.

MYELOMALACIA ; SOFTENING OF THE SPINAL CORD

The term "myelomalacia," which implies softening of the spinal cord, has been applied by some authors to those conditions of local destruction of the spinal cord consequent upon the cessation of blood supply, and especially upon thrombosis of its blood vessels, as apart from the extensive local destructions which may result from inflammatory conditions. Such a distinction does not rest upon any logical, pathological or clinical basis, for thrombosis and ischæmia make up a part of the pathological process of all traumatic, inflammatory and pressure lesions of the spinal cord, and may occur as terminal events in certain diseases of the spinal cord where vascular lesions are otherwise conspicuous by their absence. Therefore, since softening of the spinal cord may be the result of widely different pathological processes, and since it does not constitute a definite clinical entity, it will suffice in this place to refer to those maladies in which it is chiefly observed.

TRAUMATIC CONDITIONS.—As a result of the intense vibration set up by the lines of force of high explosives bursting in the neighbourhood of the spinal column, even without signs of external injury or signs of damage to the bones, the spinal cord may be found to be completely diffuent over several segments. The same result may be met with from the passage of a high velocity bullet through the spinal canal, whether the spinal cord be touched by the bullet or not ; and again, the same condition occurs from the vibration of an impact when a missile hits and lodges in the surrounding bone, without directly involving the spinal canal or cord. A slighter degree of the same condition may be seen in fracture dislocations. When, as the result of injury to the spinal column, the spinal cord is torn across, the distal segment may soften completely.

PRESSURE LESIONS.—Pressure upon the spinal cord abrogates function chiefly by producing ischæmia and, if the pressure be prolonged or severe, necrotic softening occurs, and the more readily, if there be strangling of the segmental vessels which supply the cord and accompany each nerve root, as in cases of syphilitic, tuberculous or cancerous pachymeningitis, or if there be coincident disease of the vessel walls as in syphilis and atheroma. It must be borne in mind that the pressure may be exerted from within

the cord, as, for example, by the acute œdema of the cord which is so important a factor in producing the rapid onset of paralysis in acute myelitis and in syringomyelia, where complete transverse softening may occur from the distension of a cavity. Local patches of softening from strangling of segmental vessels are one of the chief causes of non-recovery from the paraplegia of spinal caries when pressure has been relieved. In intrathecal hæmorrhage, where the blood has been allowed to form a massive clot round the lower part of the spinal cord, extensive softening may occur.

INFLAMMATORY CONDITIONS.—In acute spreading myelitis, in which the spinal cord is infected with micro-organisms secondarily to a general blood infection, as may occur in small-pox, gonorrhœa, dysentery, etc., the cord softens and may become diffuent. In acute transverse myelitis, softening depends upon the severity of the initial œdema and its duration, the degree of obliterative arteritis, and the consequent thrombosis that may occur. It may be largely avoided by the energetic and early application of anti-syphilitic treatment.

TERMINAL SOFTENING IN PROGRESSIVE DISEASES.—In certain progressive diseases of the spinal cord, extensive thrombosis of the vessels with softening may occur. For example, in a case of subacute combined degeneration, which had been under my observation for several years, complete flaccid paraplegia occurred a fortnight before death. The most extensive thrombosis of the cord was found below the eighth dorsal level, with complete necrosis of the distal segment throughout. A similar condition is not infrequently seen in paraplegia from spinal caries.

SENILE PARAPLEGIA.—This condition, which is not very rare, and in which spasticity of the lower extremities with weakness comes on gradually in later life, and does not, as a rule, reach a severe degree, has been attributed to ischæmia and even to softening of the spinal cord from arterial disease and the failing circulation of old age, by Moxon, who first described it. The pathology of these cases seems by no means certain, and there are few records of the anatomy. It seems certain that no appreciable softening can occur, on account of the slowness of the paraplegia and the absence of any sensory loss. Gowers doubted whether they were spinal in origin at all, and attributed some to the occurrence of cortical changes in the brain, while others he placed in the category of paralysis agitans. From the occurrence of definite mental failure in some of the cases, a cerebral site for the lesion is likely. Dr. Greenfield has recently examined for us a very typical case and found no changes in the spinal cord, but extensive degeneration of the pyramidal cells of the motor cortex. In one case, clinically belonging to this class, laminectomy revealed ivory-like exostoses narrowing both the spinal canal and the intervertebral foramina, and the case was obviously one of a slow-pressure lesion.

SUBACUTE COMBINED DEGENERATION

Synonym.—The Anæmic Spinal Disease.

Definition.—Subacute combined degeneration is a disease most common in the second half of adult life, of which the onset is usually insidious and the course progressive to a fatal termination. The lesions in the nervous system consist of a primary demyelination, commencing in the centre of the

white columns and affecting the long fibres first and most, and the short intersegmental fibres which lie close to the grey matter last and least. Neuroglial condensation follows very slowly upon the demyelination. The posterior and lateral columns of the spinal cord are early affected, and it is to the affection of both these columns that the term "combined degeneration" alludes. The clinical features are usually strikingly distinct, in that subjective sensations, such as tingling, numbness and burning, occurring usually at the periphery of the limbs, are early, obtrusive and persistent, and are accompanied or followed by the development of a paraplegia which may be of a spastic, or a flaccid and ataxic, or of a mixed type, according to the degree of affection of the lateral and of the posterior columns in each case.

The deep reflexes are present, exaggerated or absent, according to the relative affection of these columns. The superficial reflexes are remarkably brisk, in sharp contrast to the diminution of these reflexes which usually obtains when the lateral columns of the cord are affected. Loss of sensibility of peculiar distribution occurs, which has a "glove and stocking" distribution upon the limbs and a segmental distribution upon the trunk. In the late stages of the malady, the paraplegia tends to become complete and of the flaccid type, with loss of the deep reflexes. Anæmia accompanied by a peculiar "biscuit-like" discoloration of the skin is present in all cases at some period of the disease, with the exception of some few of the cases of short duration. This anæmia tends in every case, if life is prolonged, to develop into a pernicious anæmia which is typical, both clinically and pathologically.

Ætiology.—First met with in the third decade of life, the malady becomes increasingly frequent until a maximum incidence occurs in the sixth decade, while cases commencing in the seventh decade are not uncommon. The sexes are equally affected. Familial incidence in this disease, as also in pernicious anæmia, has been recorded by Hurst, Pincus and others. Little is known of the causal factors of the disease, and in the majority of the recorded cases the patients have been strong and healthy until the onset of symptoms. In a considerable number of cases, however, symptoms pointing to gastro-intestinal infection, such as vomiting, diarrhœa, anorexia or constipation, sometimes accompanied by fever and occasionally by jaundice, have been prominent before the onset of the nervous symptoms.

Pathology.—The essential lesion is confined to the white matter of the spinal cord and brain stem. The grey matter is unaffected, except for the changes which result from destruction of certain tracts in the white matter. The meninges and the anterior and posterior roots are normal, but some degeneration is always found in the peripheral nerves. In macroscopic appearance the spinal cord is larger than normal, since the nature of the lesion is œdematous, and there is no neuroglial condensation; and in this respect the disease differs widely from other forms of postero-lateral and scattered degeneration, for in these latter conditions shrinking of the spinal cord is always conspicuous. The degeneration usually commences in the lower dorsal region of the cord, and is first seen in the centre of both posterior columns, and soon afterwards in the centre of either lateral column, as small areas of a darker and more translucent appearance than the normal white matter. It is only at an early stage of the disease that the anatomical picture is strictly one of postero-lateral degeneration, for soon after, spots of degenera-

tion appear on either side of the anterior median fissure and in other parts of the antero-lateral columns. The degenerated areas increase in size centrifugally, coalesce with one another, reach the surface of the cord and eventually involve the whole of the white matter of the cord as seen in transverse section, with the exception of the narrow zone of short internuncial fibres which everywhere clothe the grey matter. This "annular or ferrule-like" degeneration in the lower dorsal region is highly characteristic, and occurs in no other disease.

From its starting-point in the lower dorsal region the degeneration spreads upwards and downwards in the white columns of the spinal cord, and for this reason the term "funicular myelitis" was applied to it by Henneberg. This extension depends upon the occurrence of small isolated spots of degeneration in the posterior, lateral and antero-lateral columns, which increase in size and thus join the area previously degenerated. The degeneration tends to extend upwards indefinitely, and in severe and advanced cases has been found as high as the internal capsule in the pyramidal tract.

The lesions of the white columns entail the usual secondary degenerations, both ascending and descending; but these occur late, and are often much less obvious than might be expected from the severity of the local lesions. The destruction of the axons by the local lesions also causes a series of retrograde changes in the corresponding nerve-cells, and tigrolysis, vacuolation, shrinking and neurophagy may be conspicuous, especially in the cells of Clarke's column and in the cells of Betz, which give origin to the pyramidal fibres. Kattwinkle considers that the primary spots of degeneration are determined by the vascular distribution, and that they result from disease of the perivascular lymphatics. In the development of these spots the following sequence of changes can be seen. The earliest is swelling of the medullary sheaths over a small area of the white matter. The swollen sheaths then break up by fatty degeneration, and the axis cylinders become no longer recognisable. The degenerated contents of the swollen medullary sheaths now gradually disappear, leaving nothing but the fine connective tissue of the spinal cord surrounding vacuolated spaces of varying size filled with fluid, some of which represent the spaces originally occupied by the nerve fibres, but others are formed by the fusion of several such spaces. However long standing the case may be, there is practically no neuroglial reaction with condensation or shrinkage of the spinal cord, and consequently the spinal cord remains large. Occasionally the disease is entirely confined to the posterior columns of the spinal cord. The peripheral nerves may show considerable degeneration. The muscles are conspicuously wasted in the later stages, and the muscle fibres show great diminution in size and poor striation. There is not any considerable increase of the muscle nuclei, and little or no fibrosis occurs.

Blood.—In a few instances, anæmia has been absent throughout, the hæmoglobin content and the cytology being normal; this has occurred chiefly in cases which have run an acute and fatal course in a few months. Usually the blood shows an anæmia of varying severity; the hæmoglobin ranges from 35 to 75 per cent., the lower of these figures being common: the colour index is usually above the normal, and may be as high as 1.6. Anisocytosis, poikilocytosis and polychromatophilia are common. Normoblasts are often numerous and megaloblasts may be found in numbers. A relative lymphocytosis is almost always present, and may reach as much as 55 per cent. This

change occurs early, and is helpful in the confirmation of the diagnosis of the nervous disease.

A careful investigation of the blood-changes at various stages of the disease and of the post-mortem findings in a large series of cases has proved beyond any possible doubt that the blood-changes in every case are identical with those met with in the various stages of pernicious anæmia, and that a typical post-mortem picture of pernicious anæmia occurs frequently in subacute combined degeneration. The cerebro-spinal fluid presents no abnormalities either as regards albumin, sugar or cells.

The early writers believed that the anæmia was the essential part of the disease, and that the degenerations in the nervous system were the result of vascular changes consequent upon the anæmia. This view is negatived by the facts that some cases progress to a fatal issue without any evidence of anæmia, and that in others the nervous manifestations may become severe long before any anæmia is evident; and, most importantly, no case has been recorded in the literature, nor has one occurred in the very large series examined by the writers, in which the nervous manifestations developed in a patient already under observation for anæmia. The researches of William Hunter upon the causation of pernicious anæmia suggest that a gastro-intestinal toxæmia is responsible for that disease. Rothmann has subsequently shown that the intravenous injection of pyridin in dogs produces a pernicious anæmia, and, in addition, a postero-lateral degeneration of the spinal cord. Recently Orr and Rows have shown that a similar degeneration can be produced by the local action of bacterial products upon the spinal cord, and their results have been confirmed by E. Long.

The experimental evidence and the clinical and pathological features of the disease suggest, therefore, that the anæmia and cachexia and the degeneration of the nervous system are not dependent the one upon the other, but that they are the concomitant but not necessarily synchronous results of one and the same cause, which is a toxic agent of gastro-intestinal origin. Hurst and others have shown that achlorhydria is present in nearly all the cases, and Hurst is of opinion that consequent upon the achlorhydria an infection of the duodenum with the *Streptococcus longus* occurs, and that from the resulting toxæmia both the hæmolytic anæmia and the myelolytic degeneration occur.

Symptoms.—In a large majority of instances the symptoms appear insidiously and without any exciting cause. Sometimes the onset is more rapid, and may be preceded by severe gastro-intestinal symptoms such as vomiting, diarrhœa, jaundice, malaise and pyrexia. In a few cases the onset has been so rapid as to suggest the diagnosis of acute myelitis, and in one of these which was under our observation and pathologically verified, two attacks of temporary paraplegia had preceded the onset by 8 and by 4 months respectively.

The cardinal signs may be summarised as follows: peripheral subjective sensations, which occur early and are remarkably obtrusive, are complained of in the periphery of the limbs in most cases, but may occur in the perineum, neck and back of the head and in the tongue. Sensory loss is found, which commences upon the limbs with peripheral "stocking and glove" distribution, and reaching on to the trunk ascends in segmental distribution. Astereognosis occurs in the upper extremities. Paraplegia may be (a) flaccid from the first, with loss of deep reflexes; (b) spastic, remaining spastic throughout

(rare); (c) spastic, changing to flaccid paralysis with loss of the deep reflexes. (This change from the spastic to the flaccid condition may take place at any stage of the disease.) Both forms of paraplegia are accompanied by marked ataxia. Girdle sensations, lightning pains, fixed pains, gastric crises, exaggeration of superficial reflexes, are all encountered. Sphincter paralysis is late. Loss of sexual power is early. There are muscular wasting and lowering of electrical excitability of general distribution in the paraplegia region. Anæmia, which may be absent throughout or may become apparent at any period in the course of the disease, is conspicuous at the time of the onset of the nervous symptoms in about one-half of all cases.

Peripheral subjective sensations are so constantly the earliest symptom, so discomforting to the patient and so persistent, as to form a most distinctive feature of the disease. These sensations are variously described, but tingling and numbness are the most common. Creeping sensations, smarting, burning, icy coldness, tightness and pain are all common. These sensations are usually felt first upon the tips of the fingers and toes, and subsequently spread up the limbs. Lightning pains, indistinguishable from those of tabes, occur in many of the cases. A girdle sensation is the rule, and it is sometimes painful.

Sensory loss commences at the periphery and is distributed in "glove and stocking" fashion. It extends on to the trunk as time goes on, and there seems limited by the intersegmental lines. The muscle sense and sense of position are among the earliest of the sensory perceptions to disappear. Generally speaking, sensibility to pain and temperature are lost earlier, and to a greater extent than is sensibility to touch, and, as the sensory loss spreads up the trunk, the loss to pain precedes the loss to touch. In the late stages of long-standing cases, the sensory loss is likely to become absolute to all forms.

The paraplegic signs usually follow the appearance of the subjective sensations, but they may be the first evidence of the disease. They appear most often insidiously, but sometimes rapidly. The patient first notices that the legs are easily tired, that he drags the feet in walking, or that he walks unsteadily in the dark, or that he falls forward into the basin when washing himself. Slight rigidity of the lower extremities, with weakness, especially of the dorsiflexors of ankles and toes will be found, with increase of the knee-jerks, ankle-jerks, foot clonus, a tendency to pes cavus and an extensor type of plantar reflex. The defects of co-ordination are shown by the loss of sense of passive movement and of position, by ataxy of movement and by Romberg's sign. Some cases, however, form an exception to the rule that spastic ataxy is a characteristic feature of the early stages of the disease, for the knee-jerk is diminished or lost early, and the clinical picture is one of ataxy with flaccid weakness throughout. Implication of the lateral column of the spinal cord is shown in such flaccid cases by the presence of the extensor type of plantar reflex. This type of case is especially rapid in course.

Very rarely the disease is confined to the posterior columns, and when this is the case, there are no signs of involvement of the pyramidal tract. In this condition of slight paraplegia the patient may remain for years able to do some work, and he may even improve, but no case has been reported in which the signs of the organic spinal disease have disappeared. We have had many patients in whom the signs have remained stationary or improved for a period of from 3 to 6 years. Such cases, however, are the rare exceptions; for,

in most cases, the paraplegia increases in severity as time goes on, but the progress is rarely uniform. Sudden exacerbations of the symptoms may occur at any time, and these are uncommonly associated with malaise, pyrexia, vomiting or other signs of gastro-intestinal disturbance and by an increase in the anæmia, as if there had been a sudden increase in the toxic condition, which is responsible both for the anæmia and for the spinal degeneration. As the disease advances, the paraplegia involves more and more of the trunk, progressing upwards. In some cases the upper extremities are affected early, and may even be the first regions to show signs of the disease. In the course of time the paraplegia becomes complete, with great wasting of the muscles and reduction of their faradic excitability, and, when this occurs, it is usual for the spasticity to disappear with the onset of a flaccid paraplegia with diminished and finally absent knee-jerks, the extensor plantar response and the superficial reflexes persisting. On the other hand, the spastic state sometimes persists to the end in spite of absolute paraplegia and total sensory loss of months' duration, and in such cases reflex flexor spasm is likely to be a most troublesome feature.

The paraplegia does not, as a rule, reach the upper limits of the region supplied by the cervical enlargement of the spinal cord, and even in the most severe cases the condition of the upper extremities is one of partial paralysis, most marked in the periphery and associated with considerable wasting of the muscles of the hands and forearms. The faradic excitability of the muscles is much reduced, and it is diminished in proportion to the wasting. In addition to the muscular wasting, there is usually conspicuous wasting of the subcutaneous fat. In late stages of the disease the general bodily wasting becomes extreme.

Loss of sexual power in the male is often an early symptom. Dysuria generally appears when the paraplegia becomes pronounced. It does not often occur in the early stages of the malady, and sometimes its appearance is delayed until remarkably late. When once established, it does not show any tendency to improve with treatment. Finally, the control of the rectum and bladder becomes completely lost.

Superficial reflexes.—The persistence of a high degree of reflex excitability from the skin of the limbs and trunk, even sometimes in the last stages of the malady, is remarkable, and contrasts strongly with the general lowering or loss of the skin reflexes which obtains in other conditions of paraplegia where the pyramidal tract is involved. This easy excitability of the skin reflexes is highly characteristic of the disease. The plantar reflexes assume the extensor type early, and this remains throughout, and in most cases this extensor response is the first unequivocal sign of organic disease to appear.

Deep reflexes.—These are usually increased and may persist in active state until the end. More commonly they are increased at first and become lost when the paraplegia becomes severe. Less commonly they are absent throughout the course of the disease, and in rare cases they may be absent at first and subsequently reappear and become brisk. The reasons for this variability in the deep reflexes in different cases are not difficult to understand. The lesion in the posterior columns tends to abolish the deep reflexes, and if the lesion be major in these columns or confined to these columns, the deep reflexes will be diminished or absent. The lesion in the lateral columns causes exaggeration of the deep reflexes in greater degree than the diminu-

tion caused by the posterior column lesion, so that with lesions of both these columns the deep reflexes are still exaggerated. When the degeneration destroys all the long white columns of the spinal cord, the deep reflexes are lost as in total transverse lesion of the cord, and the change from the spastic to the flaccid state, with loss of the previously exaggerated deep reflexes, occurs when all the long white columns are involved. The reappearance of the deep reflexes, at first absent, means that the lesion was first confined to the posterior, and subsequently attacked the lateral columns.

Trophic changes in the nails and skin, vasomotor disturbances in the periphery of the limbs, and bedsores, are of common occurrence. Soft translucent œdema of the extremities and trunk is frequent, especially when the anæmia is severe, and is dependent upon the anæmia and upon the impaired innervation of the paraplegic region. Severe and painful local œdema, disappearing within a few hours, has occurred in three cases under our observation.

General mental deterioration, mild delirium, drowsiness and torpor frequently occur in the later stages of the disease, and are referable to the anæmia and the toxæmia, and possibly also to widely spread cell changes in the cerebrum. General convulsions have been reported in a few cases.

Dimness of vision is common when anæmia and debility are severe. Papill-œdema of slight degree is sometimes met with, and doubtless in relation to the anæmia. Optic atrophy has been reported in a good many cases. Small retinal hæmorrhages are not uncommon. A minor degree of nystagmus is the rule, and may depend upon the involvement of the cervical spinal cord, all lesions of which seem to be regularly associated with nystagmus, or this may be attributed to affection of the cerebellum, for changes in the Purkinje cells of this organ have been repeatedly found. The pupils may be small, irregular, unequal, and react poorly to light, and there may be narrowing of one or both palpebral apertures and sometimes marked enophthalmos, all these signs resulting from interference with the sympathetic mechanism in the lower cervical region of the cord. Herpes is not infrequent. It may occur anywhere, and has several times affected the distribution of the trigeminal nerve. A hæmorrhagic lesion of the sensory ganglion has been found.

Although anæmia is one of the most characteristic features of subacute combined degeneration, since it occurs in every case of long duration at some time or other, and since it is sufficiently striking as at once to suggest the diagnosis in at least two-thirds of all the patients when they first come under observation for nervous symptoms, yet it may be absent throughout the course of the disease in a rapid case, and its appearance may be delayed until several years after the disease of the nervous system is manifest. The anæmia in almost every case is identical in every respect with pernicious anæmia. Of those cases in which the blood picture is not typical, nearly all show megalocytosis, with a relative lymphocytosis and a high hæmoglobin index, as do early cases of pernicious anæmia, and it may be said with certainty that the longer the patient survives, the greater the likelihood of typical pernicious anæmia developing. The spleen has been enlarged in many cases, and the marrow of the bones is typical of pernicious anæmia, as may be also the iron reaction in the liver and the changes in the myocardium and other muscles. As in pernicious anæmia, the tongue is clean, and this occurs so

regularly that any appearance of furring of the tongue may justly be said to exclude the diagnosis of this disease. Fractional test meals show an absolute achlorhydria, or a relative achlorhydria, in the same proportions as do cases of pernicious anæmia. The colour of the skin is often peculiar and striking, even when anæmia is not severe, and is best described as "biscuit-coloured." A bright malar flush upon this yellowish biscuit-coloured background gives a characteristic and vivid facial aspect in the earlier stages of many of the cases. The symptoms and signs common to all anæmic states, breathlessness, headache, cardiac and venous murmurs and œdema, are commonly present, but hæmorrhages are uncommon. Syncopal attacks may occur. Irregular pyrexia is almost invariably present at some period in the course of the disease, and this quite apart from fever-producing complications, such as cystitis and bedsores. In the later stages progressive emaciation is constant, and if life be prolonged it becomes extreme.

Course.—The duration of the disease varies within wide limits from 6 weeks to 10 years or more. The average duration is under 2 years. In cases of long duration the symptoms remain slight during a large proportion of the time, and such patients may improve somewhat and continue light employment for years. Other cases show a rapid downward course with no tendency to temporary arrest. Rapid exacerbation of the symptoms with a quickly fatal issue, may occur at any time. It is unusual for any improvement to occur when once the patient is bedridden. Not infrequently a patient who has reached the stage in which the disease is usually fatal, survives in a pitiable condition for many months. Death occurs from general exhaustion consequent upon the toxic state. Cystitis and bedsores can hardly be avoided in the later stages of the disease, for the vitality of the tissues seems too low either to resist the advent of micro-organisms or to allow of any healing process.

Diagnosis.—In the earliest stage, and before the appearance of any definite sign of organic spinal disease, there may be such disability as to suggest the diagnosis of functional paraplegia. This statement is true of many organic diseases of the spinal cord, and especially of disseminate sclerosis and spinal tumour. When organic signs appear, it is especially from disseminate sclerosis, spinal tumour and tabes dorsalis that the diagnosis has to be made. The preponderance of the peripheral subjective sensations, and the presence of a florid complexion with anæmia, should always suggest the diagnosis. Slight spastic ataxy is the common clinical picture of subacute combined degeneration, of disseminate sclerosis and of spinal tumour. Peripheral sensations and peripheral numbness are not features of disseminate sclerosis, and the presence of peripheral sensory loss should always challenge that diagnosis, whereas diplopia, nystagmus, transient amblyopia and intention tremor are not early symptoms of subacute combined degeneration. Spinal tumour is especially distinguished by a sharp line of sensory loss, transverse to the axis of the body, which does not spread up from below in slow fashion.

When subacute combined degeneration commences with flaccid ataxy and loss of the deep reflexes, the distinction must be made from tabes dorsalis. The extensor plantar reflex, which is almost always present in the former disease and which is rare in early tabes, the entirely different distribution of

the sensory loss in the two diseases, the loss of power in subacute combined degeneration, and the results of the examination of the blood and cerebro-spinal fluid for syphilitic reactions and of the latter fluid for lymphocytosis, are important aids in the differential diagnosis.

In the well-developed stages of the disease, its recognition presents no great difficulty. Attention is quickly attracted by the conspicuous *anæmia* and biscuit-coloured skin. Following a period of slight paraplegia, often lengthy, the steadily increasing paralysis of the lower extremities, with perhaps sudden exacerbations, producing complete and lasting helplessness, the characteristic distribution of the sensory loss which spreads upwards towards the cervical region, the severe lightning pains, the irregular pyrexia, the *anæmia* and the relatively late onset of sphincter trouble serve to separate this disease from other forms of paraplegia. The change from the spastic to the flaccid type of paraplegia with loss of the deep reflexes and persistence of the extensor response, which occurs in many of the cases in the late stages, is highly characteristic.

The distinction from the following diseases which are grouped together as conditions of postero-lateral degeneration does not, as a rule present much difficulty: (1) Friedreich's disease and other forms of hereditary ataxy; (2) *tabes dorsalis* with diffuse sclerosis; (3) *tabes dorsalis* with pyramidal degeneration; (4) amyotrophic lateral sclerosis with posterior column degeneration; and (5) other forms of systemic combined sclerosis. The symptomatology of most of these conditions departs so widely from that of the disease under consideration, as to leave little possibility of confusion. The forms of *tabes* with pyramidal degeneration, however, require very careful differentiation as so many clinical features are common to the two diseases. The peculiar distribution of the pain sensory loss in *tabes*, the manner of advent and the general grouping of the symptoms and signs, the positive Wassermann reactions in blood and cerebro-spinal fluid, and the presence of lymphocytosis in the latter fluid, will usually serve to prevent error. It must be borne in mind that very profound *anæmia* may occur where there is syphilitic disease of the liver. In one case under the writers' care, the advent of lateral column changes and of syphilitic hepatitis with profound *anæmia*, in a case of *tabes*, gave a clinical picture closely resembling that of subacute combined degeneration.

Prognosis.—There is no evidence that recovery from this disease occurs in any of its stages. The temporary improvements which may occur are improvements in the general health and in the *anæmia*, rather than any lessening in the gravity of the nervous manifestations. Speaking generally, the duration of the disease is inversely proportional to the rapidity of the onset and development of the symptoms. Many cases remain for a long time with slight symptoms, able to follow light occupations, but in every case a rapid exacerbation may occur, heralding a quickly fatal issue. The more severe the *anæmia*, the sooner may the fatal result be expected. Those patients in whom a spastic state persists, survive longer than those who become flaccid.

Treatment.—In those cases which show *anæmia*, the administration of liver or liver extract has its customary dramatic effect in restoring the blood, and it certainly has also the effect of lessening and delaying the signs of degeneration within the nervous system. Previous to the introduction

of liver feeding we found that thyroid extract had a remarkable effect in removing the anæmia, and that it could be tolerated by patients suffering from subacute combined degeneration in very large doses, even as much as sixty grains a day. Careful attention to any septic conditions of the mouth or pharynx and to any form of gastro-enteritis or possible source of toxic absorption from the intestine, seems to yield some result in slowing the progress of the disease. To this end the use of intestinal antiseptics should never be omitted. Naphthalene tetrachloride, in 10-grain cachets thrice daily, and hexamine are of the greatest value. The more advanced the stage of the disease is, the less result may be expected from any form of treatment. Any suppurative condition of the body should be energetically treated. Every care should be taken to delay the advent of bedsores and cystitis. When present, these are often amenable to treatment in the early stages of the disease and in less acute cases, but in the more acute cases and in the later stages they are inevitable and the bodily vitality is too low for any reparative process to take place. Lightning pains and other pains are relieved by such analgesics as aspirin, acetanilide, pyramidon, phenazone, etc. Reflex flexor spasms are among the most troublesome of the symptoms, since their frequent occurrence denies sleep to the patient, and they are most important factors in the occurrence of bedsores. The remedy which seems to have most effect in checking these spasms is veronal.

PROGRESSIVE MUSCULAR ATROPHY

Definition.—A disease of gradual onset which may develop at any age from puberty onwards, and in which the anatomical findings consist invariably, whatever be the clinical picture, of three orders—(1) a progressive degeneration, shrinkage and disappearance, cell by cell, of the upper motor neurons or cells of Betz in the ascending frontal convolution, with consequent degeneration of the corresponding fibres in the pyramidal tracts; (2) a similar atrophy, cell by cell, in the lower motor neurons with corresponding degeneration of motor fibres in the peripheral nerves and atrophic degeneration of the muscles innervated by the affected cells; (3) a diffuse atrophy of the white matter of the spinal cord, the posterior columns conspicuously excepted.

A most mysterious feature of the disease is the non-correspondence between the anatomical findings and the symptomatology. In the first place, though the upper motor neuron lesion is constant in all cases, many cases run their course without the slightest external evidence that the pyramidal system is involved. Secondly, no symptoms develop corresponding with the very extensive degeneration of the anterior and antero-lateral columns of the cord in any of the cases.

The clinical picture is one of gradually oncoming weakness and disability, due either to atrophy of the muscles from the lower motor neuron lesion, in which case the paralysis is flaccid and atrophic, or to spastic paralysis of the muscles from the upper motor neuron lesion, in which case the paralysis is spastic without atrophy, or to the combined lesion of both upper and lower motor neurons, in which case the paralysis is both spastic and atrophic, and the muscular atrophy never becomes complete. Fibrillary twitchings of

the muscles are always present, and form an important diagnostic feature. Any of the skeletal muscles may be affected from the ocular muscles to those of the feet.

The clinical aspect varies greatly according as the incidence of the palsy is upon the muscles supplied by the brain stem, or upon the muscles of the trunk and limbs, and again, according as the atrophic element or the spastic element is present alone, or as both coexist in the same region or in different regions of the body.

The following are the usual clinical types, but it must be borne in mind that every transition between these types may be met with :

(A) With incidence upon the muscles supplied from the brain stem ; Progressive bulbar paralysis : 1. Pure atrophic bulbar paralysis. 2. Spastic atrophic bulbar paralysis. 3. Pure spastic bulbar paralysis.

(B) With incidence upon the muscles of trunk and limbs : 1. Pure atrophic type—(a) Local and slowly progressive ; (b) general and rapidly progressive. 2. Spastic atrophic type ; amyotrophic lateral sclerosis—(a) The spasticity and atrophy are coincident in the same muscles ; (b) the atrophy affects the upper limb and the spasticity the lower limb. 3. Pure spastic type. This is more commonly seen as an early stage of amyotrophic lateral sclerosis, where the spasticity of the lower extremities precedes the atrophy of the upper extremities by some months or years.

(C) Mixed bulbar and spinal forms.

Ætiology.—The earliest age incidence has been at 12 years, and several cases have been recorded which developed the disease at that age. As age advances the incidence of the malady becomes more frequent, until it attains a maximum between the ages of 30 and 40 years, after which there is a slow decline. It does not commonly commence in advanced age, but one case has come under the writers' observation which commenced at the age of 77 years. Males are affected three times as frequently as females, but in the cases occurring before the age of 25 years, the females predominate. Heredity only rarely influences the disease. Injury has often been alleged to be an exciting factor in the development of this disease, and there are very many cases recorded which seem to support this contention. We have made a careful analysis of many cases in which there has been a history of injury which have come under our observation and also of those in the literature, and have found that it is always a trivial injury, such as a slight knock, bruise or strain, and never a severe injury, which has preceded the appearance of progressive muscular atrophy. This one fact clearly proves that injury cannot truly be in causal association with the disease, and, further, there is no conceivable pathological process by which a trivial injury unaccompanied by any infective process, can bring about a universal and rapidly fatal dissolution of the nervous system. The probability is that the injury is in many cases due to the slight clumsiness and disability often produced by the oncoming disease, and that in other cases it is simply coincidental. Syphilis seems to be in definite causal relation with some of the cases. A positive Wassermann reaction, both in the blood and in the cerebro-spinal fluid, is found in a much larger proportion of the cases than give any history of syphilitic infection. Further, quite a number of instances of the supervention of a typical progressive muscular atrophy in cases of tabes has been observed and recorded at the National Hospital,

London. It has been freely stated that progressive muscular atrophy of syphilitic origin differs from the non-syphilitic forms in its lack of symmetry and in its course; but this certainly does not hold good for very many of the cases which show a positive Wassermann reaction. In a large majority of all cases of progressive muscular atrophy, no causal factors whatever can be discovered.

Pathology.—To the naked eye, a cross-section of the spinal cord may show some diminution in size of the ventral horns, which often present a curiously pink or rose-coloured appearance. The essential lesion is a primary degeneration of the cells of the ventral horns of the spinal cord and in the homologous motor nuclei of the brain stem, namely, the hypoglossal, facial, trigeminal and oculo-motor nuclei. Coupled with the degeneration of the lower motor neuron, is a degeneration of the upper motor neurons of the pyramidal system. In the ventral horn cells the degeneration is evidenced by a gradual shrinking in size of the cells, which lose their dendrites and become oval or spherical in shape. The Nissl bodies slowly disappear, and only in rare and rapid cases is definite chromatolysis seen. The nuclei dwindle and become irregular and distorted. Very striking and constant is a great increase of the yellow, intracellular pigment, which is usually present in a single mass near the nucleus or at the pole of the cell. As this pigment increases in bulk, it gradually displaces the nucleus and the other elements of the cell, until the degenerate cells come to consist of a mass of pigment contained within the cell wall, with a distorted nucleus lying to one side. Invasion of the pigmented cell remnants by neurophages completes the destruction, and in a late stage groups of such neurophages laden with nerve-cell pigment alone mark the site from which the nerve cell has disappeared. Consequent upon the degeneration of the ventral horn cells the reticulum of myelinated fibres in the grey matter of the ventral horn disappears, the collaterals coming from the dorsal roots alone remaining intact.

The dorsal and lateral horns are almost invariably intact, but degenerative changes are sometimes seen in the cells of Clarke's column, from which degeneration of the spino-cerebellar tracts necessarily results. The affection of the motor nuclei of the brain stem in the bulbar cases is in every way similar to that of the ventral horns. The degeneration of the motor nerves which take origin from the degenerate ventral horn cells, often proceeds *pari passu* with the degeneration of the cells. But in some cases this is conspicuously and very mysteriously not the case; for, though there may be intense degeneration in the ventral horn cells, in the intramedullary motor roots and in the muscles, there may be complete absence of any signs of degeneration in the motor fibres of the extramedullary roots and peripheral nerves.

The affected muscles are soft and toneless, and the muscle fibres are found irregularly degenerated, bundles of normal and of degenerating fibres, until the atrophy is complete, being found side by side. The characteristic change is shrinkage of the affected fibre to a calibre much less than normal. The transverse striation usually persists, and the muscles stain much more deeply with logwood than is normal. The nuclei are much increased, and as the degenerating fibres waste and disappear completely, the positions which they originally occupied are marked by clumps of such nuclei which remain in the connective tissue. As is usual in all slow tissue degenerations, fibrosis and local arterial disease accompany the atrophy of the muscle fibres.

The pyramidal neurons (cells of Betz), which characterise the precentral cortex, undergo a degeneration very similar to that of the ventral horn cells, but with this difference, that the earliest structural changes are found in the most distal part of the pyramidal fibres, and that subsequently these fibres die back towards their cells of origin in the cerebral cortex. The degeneration of the upper motor neurons never proceeds to the complete destruction of anything like all the pyramidal fibres.

As has been emphasised above, there is invariably a very considerable diffuse atrophy of the ventro-lateral columns of the spinal cord, and this is usually more marked in the shorter fibres which surround the ventral horn, and which take origin from the smaller cells of the dorsal portions of that horn, and connect the segments of the spinal cord at different levels one with the other. Degeneration of nerve fibres is found also fairly constantly in the ventral commissure, in both spino-cerebellar tracts, in the fillet, tecto-spinal tracts, rubro-spinal tracts, in the dorsal longitudinal bundle and in the mesial part of the corpus callosum, the degeneration in the latter position being presumably that of collaterals of the pyramidal fibres.

The pathological nature, therefore, of progressive muscular atrophy is a widely scattered degeneration of nervous elements not even confined to the motor systems, though these are in the main affected, since the afferent spino-cerebellar tracts are constantly found degenerated, from some unknown cause.

Symptoms.—The following description of the clinical features is based upon an analysis of 500 cases which have come under observation at the National Hospital, London. The onset is in most cases very gradual, but it may be more rapid, and severe incapacity may result in the course of a few months. In rarer cases, a severe degree of paralysis may develop in the course of a few days, and in such cases it is not uncommon to see the most remarkable temporary improvement. The nature of the onset, as a rule, indicates the course which the malady will pursue. A very slow onset is followed by a very slowly-advancing disease, often interrupted by long stationary periods, whereas the more rapid the commencement, the quicker will be the advance and the sooner will a fatal issue occur. Accompanying and sometimes preceding the onset, and not infrequently conspicuous during the early states of the disease, are certain sensory symptoms which, from the confusion in diagnosis they may cause and from the scant attention which has been paid them in descriptions of the malady hitherto, deserve emphasis. These symptoms are confined to the regions where the wasting first appears, and consist in a subjective feeling of stiffness and uselessness, much increased when the limb or the body is cold. Or there may be dull aching pains, intermittent neuralgic pains which may be severe, or a sensation of coldness or numbness which may be intense. Less commonly, tingling may be present. Painful cramp in the muscles which are about to be affected is comparatively common. These sensory symptoms, though confusing at first, are always transient, and disappear as the disease progresses, with the exception of aching pain and painful cramps, which may recur from time to time.

The *muscular wasting*, which constitutes the most characteristic feature of the disease, may commence in any group of the skeletal muscles whatsoever. It may be first manifest in such rare situations as the facial muscles, intercostal muscles, muscles of the back and abdominal muscles. The

commonest situation is in the muscles of the upper limb, where the distal (intrinsic muscles of the hand) or the proximal muscles (deltoids, spinati, etc.) are first affected in about an equal number of cases. In the hand, the muscles of the thenar eminence are the first to waste, and this is followed by atrophy of the hypothenars, of the lumbricals and of the interossei with the usual flattening of the palm, exposure of the flexor tendons in the palm from loss of the bulk of the lumbricals, hollowing of the interosseal spaces and a tendency to the "griffin's paw" attitude of the hand. The *main en griffe* is never so marked in this disease as in paralysis of the ulnar nerve, syringomyelia, etc., because the wasting soon affects the long flexors of the fingers, and further contractures of the affected muscles are not well marked in progressive muscular atrophy. As the wasting spreads to the muscles of the forearm, the flexors are usually affected before the extensors.

When the upper arm is primarily affected the wasting is first seen most often in the deltoids, whence it spreads upwards, involving the spinati and the muscles attaching arm to scapula, and arm and scapula to trunk. Among these muscles some tend to escape the atrophy relatively, or to be affected much later than others, and these are the triceps, the latissimus dorsi, the lower half of the pectoralis major, the levator anguli scapulæ and especially the upper half of the trapezius, which for this reason was called "ultimum moriens" by Duchenne. In the limbs the wasting always commences in one limb, but soon spreads to the corresponding limb of the opposite side and tends ultimately to become symmetrical. The attention of the patient may be first drawn to his malady by the altered appearance produced by the atrophy, and this is more common when the commencement is in the hands, where the subcutaneous tissue is thin and the region constantly in view. Or the disability consequent upon the weakness may be noticed first, and this is always the case where the commencement is in the bulbar muscles, and usually also where the muscles of the legs, proximal muscles of the arms and trunk muscles are first involved. Lastly, the fibrillation may be so marked as first to attract notice.

The *loss of power*, which accompanies the muscular wasting, is, as a rule, commensurate with the wasting, and does not become absolute until the atrophy is complete. To this rule, however, there are two very important exceptions. In the first place, when the affected muscles are both tonic from the upper motor neuron lesion and atrophic from the ventral horn-cell lesion—the tonic atrophy of Gowers—the loss of power is always much greater than can be accounted for by the degree of wasting present. It is a remarkable and entirely unexplained fact that when this tonic atrophy is present the muscles never completely waste, whereas in flaccid atrophy they waste completely, if the patient survives sufficiently long. In the second place, and in a minority of cases, a complete flaccid paralysis, often of considerable extent, involving perhaps all the muscles of the hand and forearm or all the muscles of the shoulder and upper arm, occurs as the initial phenomenon, and precedes any sign of wasting. This initial flaccid paralysis without wasting, generally comes on rapidly. It is not accompanied by any fibrillation, and often it remits to a very considerable extent before any wasting or fibrillation appears. When the disease commences with initial flaccid paralysis without wasting, it is usually rapid in its course, any temporary improvements notwithstanding. This initial flaccid paralysis without

wasting, especially if it improves temporarily, may give rise to great difficulty in diagnosis, for it generally occurs in one limb only, and its rapid development, and in some cases a conspicuous improvement, may give rise to the impression of a gross organic lesion of the ventral horn or ventral roots, and to hopes of recovery which are falsified later.

The disability which progressive muscular atrophy produces in the limbs is always much more marked when the limbs are cold, and conversely. There may be an appearance of vasomotor paralysis, redness, blueness and some swelling of the periphery, but this seems to occur much more as the result of the continual pendent position of the hands, when the muscles, which flex the elbow and which raise the shoulder, are affected, than as the result of any definite vasomotor palsy. In the regions where the muscular atrophy is apparent, the fat and subcutaneous tissues also waste slowly and progressively, and in all but the rapidly progressive cases this wasting is conspicuous.

Next in order of frequency to initial wasting in the upper extremities, comes the incidence of the disease upon the muscles concerned in facial expression, articulation, mastication and deglutition, and in lesser degree upon the muscles of phonation; and the disease may be confined to these muscles throughout the whole of its course. From the widely different clinical picture resulting, and from the fact that all these muscles are supplied from the brain stem and upper two segments of the spinal cord, this form of the disease has borne the name of "progressive bulbar paralysis," or "labio-glosso-pharyngeal paralysis." Here the wasting commences in the intrinsic muscles of the tongue and spreads thence to the orbicularis oris, to the extrinsic muscles of the tongue, pharynx and larynx, to the muscles of mastication and, eventually, but in less degree, to the facial muscles generally; but only in rare cases are the oculo-motor muscles affected.

The intrinsic muscles of the palate, the constrictors of the pharynx, the intrinsic muscles of the larynx, and the muscle of the œsophagus are little affected. We have, in a series of cases, examined microscopically all the muscles concerned in the acts of deglutition and phonation, and have found these muscles conspicuously exempt from atrophy. This seems at first an anomalous and astonishing fact, considering how great and important are the troubles with deglutition in bulbar paralysis. But the anomaly disappears at once when one considers that the muscles which are concerned with buccal deglutition are the muscles of the tongue, those forming the floor of the mouth, including the mylohyoid and the digastric, the muscles which raise and lower the jaw, and those of the lips. Further, the muscles which are most important in pharyngeal deglutition are those which raise and lower the hyoid bone and larynx as a whole, and these are the stylohyoid and stylopharyngeus, the palatoglossus and palatopharyngeus, the geniohyoid, thyrohyoid, sternohyoid, sternothyroid and omohyoid. All these muscles are early and severely affected in bulbar paralysis; and when they fail, the intrinsic muscles of the palate are unable to shut off the naso-pharynx, the constrictors of the pharynx are entirely unable to perform the act of deglutition, and the intrinsic muscles of the larynx—though phonation is never lost—are unable, since the larynx is unfixed by the extrinsic muscles, to modulate the tone of the voice. The very active pharyngeal reflex and the well-known great difficulty in using the laryngoscope on account of spasm of

the pharynx in the subjects of this disease, are very good clinical evidence that the pharyngeal constrictors are not affected.

The earliest physical sign of bulbar paralysis is the loss of the finer movements which are essential for correct articulation, and consequently a slurring dysarthria develops and increases, and the consonants become less and less distinct until they are inaudible. The failure of the palate to close upon the posterior pharyngeal wall begets a nasal element in the voice. Later, the patient becomes unable to interrupt his blast at any of the stop positions, and his utterance becomes a long, moaning, monotonous, inarticulate sound. His phonation remains, but he cannot alter its pitch nor divide it into parts of speech, except by taking a fresh breath. The orbicularis oris is early affected, and the lips lose their firmness and become thin, and as they weaken, the unopposed retractors of the angles produce a wide, straight mouth, both at rest and in emotional action. Whistling and pursing up the lips become impossible, and ultimately there is much dribbling of saliva, for this can neither be retained by the lips nor swallowed. The tongue shows fine fibrillation, and as it wastes its point, becomes rounded, and is protruded with difficulty. Its surface becomes dimpled and faceted, and in the end consists solely of the covering mucous membrane, the glands and the fibrous tissue, and lies motionless in the floor of the mouth, resembling a crinkled mushroom. The muscles of mastication all become affected. The bite becomes feeble and the mouth cannot be opened against resistance. In the late stages the jaw drops and the mouth is constantly open. The combined weakness of tongue and buccinators makes it very difficult for the patient to keep his food between his teeth in mastication, and often he aids his disability by digital pressure upon the cheeks. Nasal regurgitation is not uncommon. The difficulty in swallowing is greatest with fluids, for these require quick action, and is next greatest with lumpy solids, for these necessitate powerful action. It is least with food of a porridge-like consistency, and this should be carefully borne in mind in feeding the patients.

The other muscles of the face are affected later and to a much less severe degree than is the orbicularis oris. It is as if there were a physiological selection on the part of the disease for the nervous mechanism subserving mastication and deglutition. Still in the majority of cases there are bilateral general facial weakness and wasting which, with the peculiar mouth and dropping jaw, produce a characteristic facies which can be instantly recognised. If the upper facial muscles are tested by raising the eyelid with the finger against resistance, invariably they will be found to be weak. Only in very rare cases does the atrophy extend to the oculo-motor muscles. As in the paralysis of the limbs, so also in bulbar paralysis, concomitant signs of both upper motor neuron and of lower motor neuron lesion may exist. When such tonic atrophy of the bulbar muscles is present, the symptomatology and clinical appearance are the same as have been above described for the simple atrophic form, with the exception that the jaw-jerk and the other muscle-jerks of the bulbar region, which are absent in the latter condition, are brisk in the tonic-atrophic form. And, further, it must be remembered that the additional element of spastic paralysis adds greatly to the degree of the paralysis as a whole.

In less common cases of progressive bulbar paralysis the upper motor

neuron lesion alone is in evidence, and the bulbar paralysis is purely spastic. Here the symptomatology as regards articulation, deglutition, etc., is the same, and the facial aspect identical with that of the simple atrophic and tonic-atrophic forms. The muscle-jerks are brisk. The appearance of the tongue, however, is quite different; it is smooth, narrow, stiff and drawn into a narrow compass by the spasm of the muscles composing it. It appears too small for so large a mouth. There is no fibrillation, and the muscles are nowhere wasted.

The muscles of the back of the neck, the splenius, complexus, etc., are not uncommonly the first muscles to be affected with the wasting of progressive muscular atrophy. There is increasing difficulty in extending the head, which drops forward, causing a characteristic attitude, which is associated with a constant overaction of the frontales which raise the brows to clear the line of vision when the head is dropped forward, so giving rise to a permanently furrowed brow. The loss of substance in the muscles of the back of the neck, together with the dropping forward of the head, causes the lower cervical and upper dorsal spines to stand out in undue prominence, and to give an appearance approximating to that of an angular curvature.

Primary affection of the lower extremities is much less common than that of the upper extremities, bulbar region or neck muscles. The anterior tibial and peroneal muscles are usually attacked first, and less commonly the quadriceps. The clinical type is that of flaccid atrophy in most of the cases. Tonic atrophy, which is so common in the upper limbs and in the bulbar region, is rare in the legs. Spasticity without atrophy from the upper motor neuron lesion alone is very common in the lower extremities. It forms a characteristic part of the frequently occurring clinical type of amyotrophic lateral sclerosis, in which the upper extremities or bulbar region are affected with atrophic paralysis, and the legs with spastic paralysis. In this common combination the atrophic paralysis is usually of the tonic and much less frequently of the simple flaccid type. Spasticity from the upper motor neuron lesion may develop in the lower extremities long before there are any signs of atrophic paralysis elsewhere from the lower motor neuron lesion, and such cases present the physical signs of a primary lateral sclerosis. Therefore, it cannot be too strongly borne in mind that any case presenting the features of a primary lateral sclerosis in an adult may eventually prove to be one of progressive muscular atrophy.

Wherever the site of commencement of progressive muscular atrophy may be, it invariably spreads to other regions, sometimes slowly and with periods of arrest which may last for years, sometimes with remarkable rapidity. The manner of spread is usually in terms of the contiguity of the affected elements in the nervous system; but it is sometimes in terms of the physiological association of the muscles as is commonly seen in the bulbar forms of the malady. When the disease is definitely installed the appearance of fibrillation, in any muscles otherwise unaffected, is a sure sign that atrophy will shortly commence in those muscles.

According to the method of advance shown by the disease, cases of progressive muscular atrophy fall into two groups which it is important to distinguish. In the first group, the atrophy spreads locally and slowly and remains confined to one region of the anatomy during most of the course of

the malady. These cases are always of the simple atrophic type, and they usually survive a long time. Such cases, however, tend to become general just before the end. In contrast with the local type of the affection is the group in which the manifestations, commencing locally, spread within a comparatively short time to many parts of the anatomy, or even become universal. The spread may be very rapid, and the end may occur in a few months, or it may be slower; but it is unusual for any of the cases forming this group to survive for more than eighteen months. This group comprises (1) the generalised cases of simple flaccid atrophy; (2) all the cases of amyotrophic lateral sclerosis; and (3) most of the bulbar cases.

Fibrillation is a most important symptom of the disease, and is an associate of the muscular atrophy. It seems to be the expression of degeneration which is occurring in the yet living and functioning nerve cell. It precedes the wasting of the fibres, and is a sure herald of the advent of wasting in this disease. It ceases to occur when the muscle is completely wasted, and is not seen when the atrophy is not progressing. On account of the importance of fibrillation as a diagnostic sign of progressive muscular atrophy it is important here to consider those other conditions in which it is met with clinically. It occurs in syringomyelia and in peroneal atrophy, but only when the muscular atrophy is progressing, and, therefore, it is only an occasional symptom in either disease. It is often very marked in cases of interstitial neuritis (sciatica, etc.). It occurs in a most magnified and conspicuous form in certain conditions of gastro-enteritis, and is presumably due to an intoxication, and to this form of fibrillation the term "myokimia" has been applied. It is not met with in polyneuritis, poliomyelitis, myopathy, nor in the common gross lesions of nerve trunks, nerve roots or spinal cord.

The *electrical reactions* of the affected muscles vary according to the degree of degeneration. Since normal and degenerate fibres are stimulated side by side in the affected muscle, there will be some lowering of the response to faradism with a tendency to a polar change. This is known as the "mixed reaction," and it is common to all diseases in which muscle degenerates fibre by fibre. Faradic excitability lessens as more of the muscle fibres degenerate, and when degeneration is complete all electrical excitability is lost. The excitability of the affected muscles to direct mechanical stimuli, such as percussion, is increased so long as any living muscle remains.

Contractures are conspicuous by their absence in this disease, which is thus strongly contrasted with peroneal atrophy and some other muscular atrophies. If the atrophy becomes complete in a whole limb the end result is that the limb is flail-like and without contracture.

Mental alterations are constantly present in the cases in which the bulbar region is affected. Emotional instability and hyperexcitability are the usual change. The patient is easily excited to tears or to laughter by trivial causes, and when so excited cannot control his expression of emotion. He himself feels little joy or grief during the paroxysms of laughing or crying.

Sphincters.—In the majority of the cases these are not affected, but every now and then dysuria in any of its forms occurs, and it may occur early in the course of the malady, and it may be severe. Loss of sexual power is very common.

Reflexes.—The superficial reflexes are modified in this disease, on the one hand by spasticity, when this is present, and, on the other, by the muscular

atrophy which may prevent response in the affected muscles. The pharyngeal reflex in bulbar cases is usually brisk, notwithstanding the statement to the contrary, which most antecedent writers upon this subject have recorded; but the response is not the normal response, involving all the muscles concerned in deglutition, for these are atrophied and paralysed; it is confined to the constrictors of the pharynx and the muscles of the palate, with the feeble co-operation of such of the somatic bulbar muscles as are still able to act. The abdominal reflexes are diminished or lost in the spastic cases, and in those cases where the atrophy is incident upon the muscles of the abdominal wall. The plantar reflexes are usually of the extensor type when the legs are spastic; but this does not always obtain, for there may be definite rigidity of the legs with brisk knee-jerks and foot-clonus with a persistent flexor response. The muscle-jerks disappear from the affected region in simple atrophic cases pari passu with the wasting of the muscles. In cases of tonic atrophy they are everywhere increased, even in regions where the atrophy is severe, and in this type of the malady they never disappear. The same increase of the muscle-jerks occurs in the purely spastic cases.

Diagnosis.—The malady has to be distinguished from the many conditions in which progressive weakness and wasting of the muscles occur, from those in which muscular wasting and spasticity are conspicuous clinical features, and lastly from other diseases, in which bulbar symptoms are early evidenced. Peroneal muscular atrophy very closely resembles progressive muscular atrophy, in that slow wasting and fibrillation of the muscles are the chief clinical features. The points which distinguish the two conditions are that peroneal atrophy is often a familial disease, and is apt to commence in childhood, when it is unusual for progressive muscular atrophy to begin. The location of the atrophy is peculiar, and when well marked in the periphery of all four limbs, as is common in this disease, cannot be confused with progressive muscular atrophy since the latter disease never has this distribution. Syringomyelia is easily distinguishable by the early and striking loss of pain and temperature sensibility. Cervical rib not uncommonly produces atrophy of the intrinsic muscles of the hand, and, though this is usually confined to one hand, it may be bilateral. Pain in the distribution of the eighth cervical and first dorsal roots, and some loss of sensibility, may be present. The atrophy remains local, and is never accompanied by fibrillation. The abnormal rib is easily discoverable on radiographic examination. It must be borne in mind that cervical ribs are not uncommon, and that their presence does not necessarily prove the cause of atrophy of the hand muscles, for cervical ribs may be present in progressive muscular atrophy, in syringomyelia, and in any other disease.

Arthritic muscular atrophy occurs in the regions of joints which show easily recognizable disease. Fibrillation does not occur, nor are there alterations in the electrical excitability of the wasted muscles. Myotonia atrophica is at once separated from progressive muscular atrophy by the myotonus, when this latter symptom is present. When myotonus is absent, the characteristic wasting of the sternomastoids, and of the muscles of the thighs, the age of the subject, and sometimes the presence of cataract should suggest the diagnosis.

Lesions of peripheral nerve trunks may be diagnosed by the history of a local cause, by the discovery of a palpable local lesion upon the course of

the nerve, and by the confinement of the atrophy to the distribution of one particular nerve, while often pain and sensory loss occur in that same distribution.

Lesions of the nerve roots, and especially those produced by pachymeningitis and by neoplasm in the vertebræ may cause signs and symptoms so closely resembling those of the more rapid forms of progressive muscular atrophy, as to render correct diagnosis very difficult. Such a lesion in the cervical region, for example, may give rise to wasting of the hand and forearm muscles, and a spastic condition of the legs, resembling exactly a condition of amyotrophic lateral sclerosis, without deformity or rigidity of the spine, and without pain or sensory loss. In such cases of difficulty the course of a little time will bring the advent of the conclusive symptoms of a local pressure lesion. It is important in this connection to remember that pressure upon the spinal cord results in hyperalbuminosis of the cerebro-spinal fluid, and if the lesion causing the pressure is syphilitic, there is likely also to be lymphocytosis in that fluid, neither of which conditions is found in progressive muscular atrophy. Symptoms resembling those of amyotrophic lateral sclerosis may arise from tumour involving the cervical enlargement. The latter condition becomes easily diagnosable from the not long delayed appearance of sensory loss both upon the arms and upon the trunk below the level of the lesion. Fibrillation is never present in any pressure lesion of peripheral nerve, nerve root or spinal cord.

Diagnosis is most difficult in those cases where spasticity in the limbs is the first sign of progressive muscular atrophy to appear, and where such spasticity precedes the appearance of any muscular atrophy by a long time. If it be clearly borne in mind that spastic paralysis may be the earliest, and for a time the only sign of progressive muscular atrophy, and that among the many diseases of the nervous system, which commence with the same clinical picture of spastic paralysis, a certain diagnosis cannot be made until further distinguishing signs appear, error will be avoided. The importance of the examination of the cerebro-spinal fluid in all cases cannot be too strongly emphasised.

Course and Prognosis.—The nature of the disease is to progress, and to extend its area of invasion until a fatal issue is reached. The progress may be rapid, and the end may be reached in a few months, or it may be slow, and many years may elapse before death occurs. The local types of slow onset are the most gradual in their development, and these are often characterised by periods of arrest in the progress of the disease. The generalised simple atrophic type of the disease is the most rapid, especially when it commences with severe initial flaccid paralysis without atrophy.

In the bulbar types of the disease, and in amyotrophic lateral sclerosis, the course is for the most steadily progressive. Every type will show, however, upon occasion, exacerbations and remissions, and the exacerbations are the most important, and in the bulbar types may bring about the end in a few hours. Of particular interest are rapid extensions of a flaccid paralysis, which may occur in a few hours, and which resemble, and indeed are identical, with onset of the disease with initial flaccid paralysis without atrophy, which has been already described. Whatever type of the disease be present, it tends in the end to spread and to become general.

Involvement of the respiratory muscles or severe bulbar symptoms, and

the pulmonary complications which may accompany either condition, may bring about the fatal issue. It is usual, however, for death to occur in a manner which is common to so many degenerative nervous diseases, a rapid increase of the paralysis is associated with an increasing lethargy, which soon deepens into a rapidly fatal coma. It is as if an acute toxic process occurs when the nervous degeneration becomes rapid. It is uncommon for death to occur from intercurrent maladies. The average tenure of existence after definite signs are present is under 1 year in the generalised flaccid type, and it may be as short as 2 months. Bulbar symptoms are not generally survived for more than 12 months. Localised cases of simple atrophy may live for many years. Some of the patients in whom a positive Wassermann reaction is found improve, and the disease is sometimes arrested by anti-syphilitic treatment.

The progressive character of the disease renders the prognosis grave in every case. There are some cases occurring in middle life, which are presumably cases of progressive muscular atrophy of local distribution and slow onset and course, which become finally arrested or even improve; but in the absence of pathological verification the true nature of such cases is open to doubt. Slowly progressive local cases usually last 5 years, and may live as long as 25 years from the onset. In these the malady becomes general in the end. The possibility of the occurrence of rapidly advancing generalisation always renders the prognosis uncertain.

In amyotrophic lateral sclerosis the average duration of life is not more than 2 years from the onset. When bulbar symptoms are present the average duration is under 2 years. In the generalised cases the average duration is under 1 year. Widely spread fibrillation in muscles, which are neither weak nor wasted, is the constant herald of generalisation, and renders the immediate prognosis serious. In cases where syphilis is present the prognosis is more favourable, and there is even a possibility of arrest and improvement if energetic treatment of the associated condition is provided. Rapid extension of the weakness, the advent of bulbar symptoms, involvement of all the respiratory muscles, and especially general asthenia and drowsiness are the signs which usher in the fatal result.

Complications.—By far the most common complication which is met with in cases of progressive muscular atrophy is the presence of some syphilitic lesion of the nervous system, and this may be of any nature, both local or general. *Tabes dorsalis*, associated with progressive muscular atrophy, is not uncommon. General paralysis of the insane has been noted in a few cases, as has also paralysis agitans.

Treatment.—For the most this malady seems to be entirely uninfluenced by any treatment that has hitherto been adopted. Even where syphilis is a factor in the causation, although appropriate treatment for these conditions has been applied, and improvement and even arrest may result, it is no rare thing to see no amelioration, and in some cases such treatment seems actually to hasten the progress of the disease. The value of treatment by the hypodermic injection of strychnine, which was claimed by Gowers, has not been borne out. It remains, therefore, to secure favourable conditions of life for the patient, and to maintain the general health in as perfect a state as possible. Cold, fatigue and traumatic influences, such as falls, are carefully to be avoided, as likely to increase the disability and incite extension

of the disease. Absolute rest is not essential, and adherence to light occupation where possible seems to hinder rather than to advance the progress of the disease. All tonic remedies are useful. Organotherapy has been largely vaunted; but any advantage gained therefrom is from the tonic effect upon metabolism. It has no specific effect upon the malady. Electricity, massage and passive movements are useful as giving bodily comfort to the patient, and satisfying him that something is being done for him, and that nothing has been left untried. Electricity, when strongly applied, does harm, and faradism must not be used in spastic cases. In bulbar cases, the dysphagia must be aided by avoiding liquids and solids, and by serving all the articles of diet in pultaceous form. Salivation, which is so troublesome in this condition, may be greatly helped by the administration of hyoscine by the mouth. In the rare cases where sphincter trouble is prominent, the regular administration of belladonna is of signal service. In the bedridden state cleanliness and careful attention to the skin, and to regular shifting of the patient, will always prevent the formation of bed-sores.

PERONEAL MUSCULAR ATROPHY; CHARCOT-MARIE-TOOTH TYPE OF MUSCULAR ATROPHY

This is an absolutely distinct and peculiar form of muscular atrophy, with a frequent tendency to occur in several members of the same family. It usually commences in mid-childhood, and after progressing for some twenty years or less, comes to a final arrest. The atrophy always commences in the intrinsic muscles of the feet, and is throughout strictly distal in distribution. The muscles of the face and trunk and the proximal muscles of the limbs are never affected. The atrophy leaves a peculiar elastic fibrosis in the affected muscles, so that the incapacity caused by this disease is much less than in any other form of muscular atrophy of like degree. Sensibility is often slightly affected, and there may be deep sensory loss. The essential morbid anatomy is a primary neuron atrophy of the anterior horn cells and of some of the afferent neurons in certain regions of the spinal cord.

Ætiology.—The disease usually commences between the fifth and tenth years of childhood, but it may appear as late as the fourth decade of life. Males and females are both affected. Heredity plays an important part in the incidence, although isolated sporadic cases are not uncommon. The malady often occurs in families, and has been traced through five generations; it may skip a generation and then reappear.

Pathology.—The anterior horn cells of the affected regions show a slowly progressive atrophy and disappearance, with corresponding atrophy of fibres in the peripheral nerves. The cells of Clarke's column show signs of degeneration, as do also some of the fibres of the posterior columns of the spinal cord, and especially those of the postero-lateral column. Slight degeneration in some of the fibres of the pyramidal tracts is usually found. The affected muscles show a simple atrophy of the muscle fibres, indistinguishable from that seen when a motor nerve is divided. There is a simple shrinking of the fibres, which stain progressively and more and more deeply with hæmatoxylin, lose their striation and finally disappear. Secondary fibrotic

changes accompany the atrophy, together with sclerosis of the arteries of the muscle.

Symptoms.—Muscular atrophy always dominates the clinical picture of this malady. It is always strictly distal in distribution, and this feature will almost always serve to distinguish peroneal atrophy from any other form of muscular atrophy. This is to say it does not affect one particular muscle, but the distal ends of all the muscles below a certain level on the limb, leaving the proximal ends of the muscles normal, and it advances up the limb inch by inch, the separation of the wasted portion of the muscle from the normal portion being always transverse to its length. In other words, the muscle fibres seem to waste in terms of the length of the spinal axons which supply them. The wasting commences always in the intrinsic muscles of the feet, and hollowness of the instep and thinness of the feet, together with retraction of the toes and the difficulty which the pes cavus so produced entails in fitting boots, first draws attention to the disease. As the process advances, the lower segments of the anterior tibial, peroneal and calf muscles become affected, and the limb is subsequently involved until the lower third of the thigh is reached, at which stage the disease is invariably arrested. This slow spread of the atrophy from the distal towards the proximal portion of the limb, gives rise to a most unique and characteristic feature in the appearance of the legs at the several stages of the disease. As an example, the complete atrophy of all the muscles below the middle and a well-developed musculature in the upper half of the leg, give rise to the inverted "fat bottle" calf. When the atrophy has involved the lower third of the thigh, the lower end of the femur, bare of muscle and covered only by skin and tendons, contrasts strongly with the well-developed muscles of the upper thigh, and causes the thigh to resemble an inverted champagne bottle.

Some years after the atrophy has become marked in the lower extremities, and in the usual run of cases just before the age of puberty, the intrinsic muscles of the hands and first those of the thenar and hypothenar group begin to waste, and this wasting may extend as high as the middle of the forearm. It must be borne in mind that the disease may become arrested at any period of its spread, and especially that the upper extremities often escape altogether. With the exception of the lower part of the thighs, the proximal segments of the limbs do not become involved, and the muscles of the head, neck and trunk remain unaffected.

The affected regions of the muscles waste absolutely, and leave a very elastic and not strongly contracturing fibrous tissue. The electrical excitability in the wasted regions becomes first lowered and then lost, and, in the earlier stages, may show a mixed reaction, in which there is lowering of excitability to faradism, with a tendency to an inverted polar reaction. Fibrillation of the muscles is an important sign. It is seen only when the disease is progressing, and in the muscles which are obviously wasting. It is never general, as in some cases of progressive muscular atrophy. And since peroneal atrophy is at times advancing and at other times stationary, fibrillation may be in one case conspicuous and in another never seen. It disappears entirely when the progress of the malady becomes finally arrested, and is, therefore, useful as a clinical indication of active advance of the disease. Contractures always occur, and from the nature of the distribution

of the atrophy are necessarily confined to the feet and the hands. In the feet, pes cavus with retracted toes is the rule; but sometimes, and in some stages of the disease, the feet and toes may be dropped and the feet inverted. The sphincters are unaffected. The ankle-jerks are diminished or lost in proportion to the wasting of the calf muscles. In the final arrested stage they are usually lost. The knee-jerk is always retained and is usually brisk. The plantar reflexes are usually lost early so far as any response in the foot is concerned, but some response in the upper thigh muscles, upon stimulating the plantar region, often remains. Pain, tenderness and cramp are entirely absent. Conspicuous loss of sensibility is uncommon, but slight loss of deep sensibility, loss of the vibration sense and relative tactile loss, may often be detected upon careful examination; but in rarer cases all forms of sensibility may be severely affected, or even entirely lost. As an example of the latter condition, a patient came under the writers' care in the arrested stage with complete atrophy of all the muscles below the knees, with complete loss of all forms of sensibility below the knees. Notwithstanding this complete motor and sensory loss, he was able to get about upon his legs and work, guided by sensations which reached his consciousness from the articular surfaces of the lower ends of his femurs. Perforating ulcers may be met with upon the soles of the feet, and are explained by the thinness of the feet and their deformity, which, coupled with the clumsiness of the use of the feet, lead to the formation of severe corns which break down into perforating ulcers. Loss of sensibility also is a factor in their production.

The most striking of all the clinical features of peroneal atrophy is the comparatively slight disability which the wasting of the muscles and consequent paralysis, and even the sensory loss, when present, cause. This is due to the peculiar quality of the fibrosis which succeeds the wasting. The fibrosed muscles support the joints in such a condition of unchanging, elastic stability as renders locomotion and other acts possible in a degree that is not met with in any other condition of muscular wasting. Even when a rapid increase of wasting has caused great disability, it is almost invariable to find that the advent of fibrosis in the course of time greatly lessens the disability. Thus, in a patient aged 16 years, who was unable to walk without assistance on account of the severe paralysis below the knees, a lapse of 4 years found him able to earn a good wage, working upon his feet, though there was no change in the degree of paralysis during this time.

Course.—The course is irregularly progressive for a number of years only, and the advance of the disease ceases usually in the third decade of life. Exacerbations of the weakness are likely to be followed in every case by considerable improvement, owing to the secondary fibrosis in the muscles.

Diagnosis.—Peroneal atrophy in the early stages is easily confused with progressive muscular atrophy, in that wasting of muscles and fibrillation are the conspicuous features. The onset usually in childhood and the fact that the feet are affected first, the peculiar distal distribution and the presence of any familial incidence, are important. But the only distinction which is absolute is the distribution, for progressive muscular atrophy may begin in childhood and peroneal atrophy may not appear till after middle life, and often familial relations are absent in the latter malady. In the course of time the diagnosis always becomes clear, for progressive muscular atrophy

never keeps to the classic distribution, nor is it followed by the peculiar fibrosis which characterises peroneal atrophy.

Dystrophia myotonica when commencing in the peroneal muscles may for a time closely simulate peroneal atrophy. The presence of the least sign of myotonia, the involvement of the face and the atrophy of the sterno-mastoids, will establish the diagnosis.

The usual forms of myopathy are at once separated from peroneal atrophy by the distribution of the muscular weakness and wasting, which in the former group of maladies is conspicuously upon the face, trunk and proximal muscles of the limbs, and in the latter upon the distal muscles. Peripheral neuritis is more rapid in its onset, and is apt to be associated with marked sensory disturbances, both objective and subjective, and the paralysis is in terms of individual muscles, which is not the case in peroneal atrophy.

Prognosis.—The disease has no tendency to destroy life. Complete arrest always occurs. There is invariably a tendency for the amount of disability to improve, for the reasons that the fibrosis of the paralysed muscles, which occurs in the course of time, renders the affected limbs more serviceable, and, further, that the patient learns to overcome his defects. There is never any real recovery in the affected muscles.

Treatment.—The general health should be carefully maintained, and the nutrition of the affected muscles aided by the application of massage and electricity. Care must be taken, on the one hand, to avoid over-fatigue of the affected muscles, and, on the other, to ensure such regular exercise as is compatible with their capacity. Bicycling, for example, since it employs chiefly the thigh muscles, is a better form of exercise for these patients than is walking. In no circumstances should tenotomies be performed for the deformity of the feet, for such measures tend to destroy the effect of the conservative fibrosis, so essential to the production of a useful limb. The use of any heavy mechanical supports is to be avoided above all things. Light, well-fitting boots, so as to interfere as little as possible with the exercise of the damaged muscles, are essential. Light, celluloid splints may be worn at night to assist the deformity of the feet in the advancing stages of the disease. Administration of thyroid gland and other polyglandular extracts has been recommended.

PROGRESSIVE SPINAL MUSCULAR ATROPHY OF CHILDREN ; THE WERDNIG-HOFFMANN DISEASE

This is a malady of the first year of infancy, often incident upon several children of the same parents, and characterised by the gradual development of progressive muscular weakness and atrophy, which affects the proximal muscles first and most, increases to a complete paralysis of trunk and limbs, and finally affects the bulbar muscles. The disease is invariably fatal in from a few weeks to several months. The most striking pathological changes are a progressive degeneration and disappearance of the ventral horn cells of the spinal cord, and of their analogues in the brain stem.

Ætiology.—In some of the cases the paralysis is noticeable at the time of birth, and the disease is obviously of pre-natal development. In others the children are quite healthy at birth, and the disease develops some time

during the first year of life, and most frequently within 8 weeks of birth. Though sporadic cases may be met with, yet in the majority of instances several children of the same mother are affected. Both the pre-natal cases and the post-natal cases may be met with among the children of the same mother. The sexes seem to be equally affected. No maternal ill-health during pregnancy has been noticed, and nothing is known about any other ætiological factor.

Pathology.—The most extensive changes are found in the ventral horn cells throughout the spinal cord and brain stem, and at many levels no normal cells whatever are to be seen. Tigrolysis, swelling and glassiness of the cells, extrusion of the nuclei, disappearance of the dendrites, shrinking of the cells and final disappearance is the sequence of the changes. Degeneration of the anterior roots and of the peripheral motor nerve fibres consequently occurs. These changes are not confined to the lower motor neurons, for in our cases examination by the Marchi method showed extensive degeneration throughout the posterior columns of the cord, indicating that lower sensory neurons were also considerably affected.

The muscles show intense degeneration with hypertrophy of fibres and atrophy of most of the fibres, waving, moniliform shape, hypernucleation of the spindles, general nuclear increase and fibrosis.

Symptoms.—In the cases which are pre-natal, the malady is noticed at the time of birth on account of the tonelessness, flaccidity and the poorness of movement in the trunk and proximal muscles of the limbs. In the post-natal cases there is a gradual onset of similar weakness and flaccidity in the trunk first, and in the limbs afterwards, which usually commences within six weeks of birth, but which may not appear until towards the end of the first year of life. The weakness seems always to be least marked in the periphery of the limbs, where curious, slow, involuntary movements of the fingers and toes have been noted in a good many of the cases. The paralysis is followed by a rapid and extensive wasting of the muscles, accompanied by occasional fibrillary twitchings. Since these children are not only well nourished, but often put on much fat during the illness, wasting of the muscles may not be apparent on inspection or palpation. It can, however, immediately be detected by radiography, which distinguishes sharply between fat and muscle.

As the malady progresses the trunk muscles become completely paralysed, the intercostal muscles being always paralysed before the diaphragm. The limbs become progressively weaker, and, lastly, bulbar paralysis supervenes in those cases where death has not already occurred from respiratory paralysis. The reaction of degeneration is present in the affected muscles. Sensibility may be unimpaired; but in several of my cases there has been conspicuous loss of pain sensibility over the limbs and trunk. The sphincters are unimpaired until the very last stages of the disease. The superficial and deep reflexes are lost. The ocular muscles have not been affected, and intelligence is preserved throughout.

Diagnosis.—The peculiar and striking features of the disease make the diagnosis easy, if the symptomatology be known. Amyotonia congenita presents the same helplessness and flaccidity of trunk and limbs as does the Werdnig-Hoffmann disease, and further resembles it in being sometimes congenital, and sometimes having an onset very early in life. In amyotonia

congenita, however, the paralysis is not complete, and it tends to improvement and not to progressive increase. Contractures also occur, which are not found in the Werdnig-Hoffmann disease, and, lastly, the definite spinal cord changes of the latter malady are not found in the former.

Course and Prognosis.—The course is invariably progressive, and is more rapid the earlier in life the disease commences, and it is most rapid of all in the pre-natal cases, which are usually fatal within a few weeks. With an onset some weeks after birth, life is usually continued for several months, and a few cases have been reported with an onset towards the end of the first year, in which death has been delayed until the third or fourth year.

Treatment.—No treatment is known to influence the course of the malady.

LESIONS OF THE PERIPHERAL NERVES

LOCAL LESIONS OF NERVE ROOTS AND NERVE TRUNKS

PHRENIC NERVE.—This nerve is formed by the junction of fibres arising from the third, fourth and fifth cervical segments of the spinal cord. It supplies the diaphragm. Paralysis results most often from disease of the spinal cord, but the roots may be implicated in disease of the spine, and the trunk may be injured in its course through the neck and thorax, by wounds or tumours. Bilateral paralysis occurs in lesions of the cord and spine, and in alcoholic, diphtheritic, saturnine and other forms of peripheral neuritis. Other causes usually affect one side only. When the diaphragm is completely paralysed, the normal inspiratory protrusion of the upper part of the abdomen disappears, or is replaced by retraction of this part with each inspiration. During rest, so long as the lungs are healthy, the respiratory rate does not increase, but if bronchitis or pneumonia arises as a complication, or if the patient exerts himself, the diminished reserve of respiratory power is seriously felt. When one nerve only is affected the diaphragm does not descend on that side. This is rarely detected by observation of the abdominal movements, but is easily seen on the X-ray screen. It produces no discomfort.

THE LONG THORACIC NERVE.—This nerve is formed in the substance of the scalenus medius muscle, by the union of fibres arising from the posterior aspect of the fifth, sixth and seventh cervical roots. It supplies the serratus magnus muscle. When all the fibres of this muscle contract, the scapula moves upwards, forwards and outwards. It contracts with the pectoralis major in the action of pushing forward the point of the shoulder and in the rapier-thrust movement. It also assists the deltoid in raising the arm. When it is paralysed alone, the position of the scapula at rest is unaltered, but if the trapezius and the rhomboids are paralysed as well the scapula drops, and its lower angle is displaced inwards. Paralysis of the serratus magnus is best demonstrated by causing the patient to hold the arms outstretched before him. The arm is not raised so high on the affected as on the normal side, because the scapula is not fixed and the deltoid works at a

disadvantage. Viewed from behind the deformity is characteristic. The vertebral border of the scapula stands out prominently and the hand can be pushed between this bone and the thorax—"winged scapula." On raising the arm from the side, there is difficulty in attaining the horizontal position, but the winging of the scapula is less apparent.

The nerve may be damaged by carrying heavy weights on the shoulder, by falls or blows on the shoulder, and by continued muscular effort with the raised arm. The nerve may be injured alone in gunshot wounds, but as a rule it is associated with lesion of the brachial plexus. In the cases caused by compression, severe neuralgic pains in the neck precede the onset of paralysis. Recovery is always very slow and the defect may be permanent.

BRACHIAL PLEXUS.—The brachial plexus is formed by the union of the anterior division of the lower four cervical nerves and the first dorsal nerve. It may be injured by stabs in the neck, by penetrating missiles, by dislocation of the shoulder or fracture of the clavicle, or by pressure of a tumour, aneurysm or cervical rib. Further, the nerves may be torn by forcible dragging on the arm in accidents or during delivery. In most cases the lesion is partial and the symptoms conform in the main to one of the following types.

Upper plexus paralysis.—This results from an injury to the fifth and sixth cervical roots. The muscles paralysed are: biceps, deltoid, brachialis anticus, supinator longus, supraspinatus, infraspinatus, rhomboideus, subscapularis, clavicular portion of pectoralis major, serratus magnus, latissimus dorsi, teres major. The arm cannot be flexed at the elbow (flexors of forearm), nor raised and abducted (deltoid). The movements of the wrist and fingers are not impaired. Adduction of the arm is weak (pectoralis major), and rotation is feeble or absent (spinati). On attempting to oppose the shoulders, the scapula on the affected side passes further from the middle line (rhomboideus). The hand of the affected side cannot be placed on the buttock of the sound side (latissimus dorsi).

The reaction of degeneration is often complete in the deltoid and flexors of the forearm and nearly so in the spinati. It is usually incomplete in the other muscles. Sensation is diminished or lost along the outer border of the whole limb immediately after the injury, but improvement sets in rapidly. For some time the patient experiences pins and needles and burning sensations in the affected area, which last longest in the thumb and index finger. The biceps reflex is lost. Percussion of the styloid process of the radius, instead of causing a contraction of the biceps and supinator longus, produces flexion of the fingers—inversion of the radial reflex. In this form the tendency to complete recovery is great. As a rule all the symptoms disappear completely in from 6 months to 2 or 3 years. Weakness persists longest in the deltoid and supinator longus.

Lower plexus paralysis.—This results from a lesion of the eighth cervical and first dorsal roots, or of the common trunk of the median and ulnar nerves. The intrinsic muscles of the hand and the flexors of the wrist and fingers are paralysed, and the inner border of the forearm and hand is anæsthetic. When the roots are damaged, sympathetic fibres may be implicated with the production of myosis, narrowing of the palpebral aperture, enophthalmos and alterations in sweating on the face, neck, arm and upper part of the chest, on the affected side.

Middle plexus paralysis.—This form of paralysis is a common result of gunshot injuries of the plexus. It affects the muscles supplied by the musculo-spiral and circumflex nerves—posterior cord. As the nerve to the latissimus dorsi arises from the same trunk, this muscle is often paralysed as well. In addition to these simple types, more complicated paralysees occur, in which various parts of the plexus are injured together.

In *paralysis of the inner cord of the plexus*, atrophy is confined to the intrinsic hand muscles.

Lesions of the brachial plexus show a remarkable tendency to spontaneous recovery. In many cases recovery is complete in 6 months to 2 years, in others it is partial, and some muscles remain paralysed.

THE MUSCULO-SPIRAL NERVE.—Owing to its long course, its position in relation to the humerus, and its peculiar vulnerability to compression, paralysis of the musculo-spiral nerve is one of the commonest peripheral palsies; although it is a mixed nerve containing sensory, motor and vaso-motor fibres the symptoms of an injury are almost entirely motor. In the upper arm the nerve supplies the triceps and the anconeus, in the forearm the supinators, the extensors of the wrist and fingers, and the extensors and long abductor of the thumb.

Symptoms.—Injury to the nerve is followed by dropping of the wrist and fingers. The wrist and the first phalanges are flexed. The flexion is limp and easily reducible.

When the lesion is in the axilla the whole of the *triceps* is paralysed, and extension at the elbow is lost. Occasionally in wounds of the posterior aspect of the arm the nerves to the triceps are injured, whilst the main trunk escapes. The patient is then able to extend the arm powerfully by means of the anconeus, but if he is made to raise the elbow as high as possible with his fingers on the point of the shoulder, extension of the bent forearm is impossible.

In most cases the nerve is injured in the middle third of the arm and the triceps escapes, but the supinator longus and *all* the extensor muscles in the forearm are paralysed. Partial paralysees, such as are seen in lesions of the median and ulnar nerves, are very rare. The *supinator longus*, so-called, is not a supinator. Its action is to flex the forearm, whilst the hand is in a position intermediate between pronation and supination. Paralysis of this muscle is detected by the absence of contraction when the pronated forearm is flexed against resistance. Owing to paralysis of the *supinator brevis* supination is abolished. During the movement of flexion of the forearm the biceps acts as a supinator, during extension the external rotators of the shoulder, but feebly.

Paralysis of the *extensors of the carpus* abolishes both extension and lateral movement at the wrist. The flexors of the carpus play no part in lateral movements. The *extensors of the fingers* extend the first phalanges only. Extension at the distal joints is carried out by the lumbricals and interossei. Paralysis of the *extensors and long abductor of the thumb* renders abduction of the thumb and extension of the phalanges impossible. On attempting to abduct the thumb, it passes no further than the radial border of the hand. In some cases, the second phalanx of the thumb can be feebly extended by the muscles of the thenar eminence.

Many muscles not supplied by the musculo-spiral work at a disadvantage

when the extensors are paralysed. These defects must not be mistaken for signs of injury to other nerves. Owing to the flexed position of the hand the grasp is feeble, but if the wrist is extended passively the grasp is improved. The patient cannot make a fist properly, as the thumb does not oppose the index finger and the fingers cannot be flexed into the palm, until the thumb has been moved aside by the sound hand. The movements of the interossei in abducting and adducting the fingers are also feeble while the wrist is flexed, but are much stronger when the hand is resting flat on a table with the wrist and fingers extended. The complete reaction of degeneration is often found in all the paralysed muscles from the onset. Atrophy becomes obvious in a month or two. Its extent and severity give important evidence for prognosis.

Sensory disturbances.—Subjective symptoms are rare. In a few cases, paræsthesiæ are felt on the posterior aspect of the forearm and on the dorsal aspect of the thumb. They are of brief duration, and are commoner with partial than with complete lesions. Severe causalgiæ are almost never seen in lesions of this nerve. Sensibility to light touch, superficial pain and temperature is impaired over a small area on the radial border of the hand, including the proximal joints of the thumb and first two fingers. The defect is often very slight, and is only discovered on very careful examination. Deep sensibility is rarely affected. Considering the extensive distribution of the external cutaneous branch of the musculo-spiral nerve, it is rather surprising that the sensory disturbances are so slight, when the nerve is injured above the origin of this branch.

Recovery.—It might be thought that recovery would take place in the order of the length of the branches to the various muscles. This, however, is not the case. As a rule the extensors of the wrist recover first, then the extensors of the middle, ring, little and index fingers in this order, next the supinator longus, and the extensors and abductors of the thumb last of all. On palpation of the muscles during attempted extension, contractions can be felt before any movement is produced. Other signs of impending recovery are the disappearance of automatic pronation and of the flail-like drop of the hand, also diminution of automatic flexion of the fingers after passive extension. Recovery of movement is complete when the patient is able to extend the wrist and all the fingers simultaneously or separately. After this becomes possible, restoration of power is rapid.

THE MEDIAN NERVE.—Whilst the clinical individuality of the musculo-spiral nerve is shown in the preponderance of motor symptoms and in the uniform completeness of the paralysis that follows an injury, that of the median is seen in the frequency of partial and especially of painful lesions. Isolated palsy of this nerve is infrequent except as a result of gunshot wounds and other injuries. It may be damaged by repeated violent contractions of the pronator radii teres, as in one of the forms of "tennis elbow."

Total paralysis.—The muscles paralysed are the pronators, the radial flexor of the wrist, the flexors of the fingers except the ulnar half of the deep flexor, most of the muscles of the thenar eminence (opponens, abductor brevis and outer head of the flexor brevis pollicis) and the two radial lumbricals. Stated briefly the symptoms are: inability to flex the phalanges of the index finger and the second phalanx of the thumb; difficulty in flexing the phalanges of the middle finger; defective opposition of the thumb. The appearance

of the hand in total lesions is fairly constant. The hand inclines to the ulnar side, the index and middle fingers are more extended than is normal, and the thumb lies on a level with the fingers—the ape-hand.

Pronation is incomplete and defective. The patient tries to overcome the defect by rotating the whole limb at the shoulder. Paralysis of the *flexors of the wrist* is seen when an attempt is made to flex against resistance. The tendon of the ulnar flexor alone stands out, and the hand is drawn towards the ulnar side. Even at rest, the flexor tendons are more prominent on the sound than on the affected side.

Flexion of the fingers is good in the two ulnar fingers, though weaker than normal. The index cannot be flexed at all, and the third finger only incompletely. Flexion at the proximal joint is usually good in all the fingers including the index, and flexion at this joint with extension at the last two joints is usually well done by the interossei and lumbricals. If the proximal phalanx of the thumb is immobilised, it will be seen that flexion of the terminal phalanx is abolished, owing to paralysis of the *flexor longus pollicis*.

Paralysis of the *thenar muscles* renders opposition and abduction of the thumb defective. By means of the adductor the thumb can be drawn into the palm, but as the radial fingers cannot be flexed nor the thumb opposed, it is impossible to place the tip of the thumb on the tips of the fingers. Atrophy of the muscles becomes obvious in a few weeks. The outer part of the thenar eminence is flattened, and the bulk of the muscles arising from the internal condyle is greatly diminished.

Sensory disturbances.—In almost every case there is complete anæsthesia to all forms of sensation in the two terminal phalanges of the index and middle fingers. The skin outside this area may be unaffected even in complete lesions, but in most cases sensibility is diminished in the terminal phalanx of the thumb, and to a less extent over the remainder of the radial half of the palm, including the radial side of the ring finger. The stereognostic sense is lost in the outer fingers. This defect, together with the loss of power, renders the thumb and index finger useless, and makes paralysis of the median the most serious single nerve lesion of the upper limb.

Vasomotor and trophic changes.—In many cases the skin in the distribution of the median nerve is red, dry and chapped, and the nails white or purple. It is possible that these changes are due to an associated vascular lesion.

Recovery is extremely slow and is rarely complete. Sensation begins to return before power, but the stereognostic sense is often defective, long after movement in the fingers has returned. The pronator and the flexors of the wrist recover first, then the flexors of the thumb and middle finger. Flexion of the index finger and opposition of the thumb, if it is regained at all, remains defective for several years. In searching for signs of recovery, care must be taken lest some “trick-movement,” due to contractions of healthy muscles, is misconstrued. For example, when told to flex the terminal phalanx of the thumb, the patient first over-extends and abducts, and then relaxes suddenly. The terminal phalanx then makes a slight passive movement of flexion, which may be mistaken for true active flexion. Recovery is complete when the patient is able to make a good fist with the fingers flexed well into the palm, and the thumb pressed firmly upon the dorsal aspect of the second phalanx of the middle finger.

PARTIAL LESIONS.—Partial paralysis of the median nerve is much commoner than the complete form.

Motor symptoms.—Flexion of the index finger and opposition of the thumb are most impaired. The flexors of the middle finger and of the terminal phalanx of the thumb may suffer also, but to a less degree, whilst the pronators and the flexors of the wrist often escape entirely.

Sensory symptoms.—Apart from the painful lesions to be mentioned later, sensory troubles are usually slight in partial lesions. Anæsthesia is rare, but sensibility to all forms may be diminished in the areas mentioned under complete lesions.

Vasomotor symptoms.—The skin is often cyanosed in the distribution of the injured nerve, and it may perspire more freely than in healthy parts. These changes are more distinct when the paralysis is complicated by a vascular lesion.

Recovery is naturally more rapid than in complete lesions. The order in which the muscles recover and the tests for complete return of function have been mentioned above.

PAINFUL LESIONS OF THE MEDIAN NERVE.—*Causalgia.*—In many cases the most prominent symptom of injury to the median nerve is *pain*.

Motor disturbances are always present, but are usually slight, the weakness affecting mainly the flexors of the index finger and the thenar muscles.

Vasomotor changes are a feature of this type. In many cases perspiration is diminished over the radial half of the palm, and the skin becomes dry and scaly. In others, perspiration is increased over the median area.

Sensory disturbances.—Pain comes on about a month after the injury, at first as tingling or pricking in the finger-tips and palm, later as a constant severe smarting, dragging or *burning* pain—hence the name *causalgia*. Added to the constant pain which never ceases day or night, paroxysms occur, in which the pain increases suddenly in intensity. The application of cold water gives temporary relief, and patients often wear bandages or gloves which they keep constantly moistened. Many develop a phobia of dryness. They will not touch dry objects, even with the healthy hand, the sight of another person handling a dry object increases the pain, and any rustling or crackling sound, suggestive of dryness, may bring on a paroxysm.

In severe cases the limb is held flexed at the elbow and wrist, with the hand constantly raised and the fingers extended or hyper-extended. The whole hand atrophies, and irreducible ankylosis occurs with the limb in this position. The skin of the hand is thin and dry. The fingers taper, and the nails are long, brittle, blackened and striated longitudinally. The pain reaches its acme 4 or 5 months after the injury, and then slowly declines, but the limb remains useless. Even in slighter cases, without much deformity, recovery of function is extremely slow, and is rarely complete.

THE ULNAR NERVE.—Arising from the inner cord of the brachial plexus, the ulnar nerve receives its fibres from the eighth cervical and first dorsal segments of the cord. It supplies the ulnar flexor of the wrist, the ulnar half of the deep flexor of the fingers, the muscles of the hypothenar eminence, the interossei, the two inner lumbricals, and the adductor and inner head of the short flexor of the thumb. Its sensory area is the ulnar border of the hand, the little finger and the inner half of the ring finger.

Total paralysis.—Paralysis of the *flexor carpi ulnaris* may be detected by palpating the tendons when the wrists are flexed against resistance. The limpness on the affected side contrasts strongly with the firmness on the sound side. Lateral movements of the hand are unaffected, as these are carried out by the extensors.

Paralysis of the ulnar portion of the *flexor profundus digitorum*. In making a fist flexion of the index finger is perfect, and that of the middle finger good, whilst in the ring and little fingers it is absent or very feeble. This weakness is best seen when flexion is attempted with the index and middle fingers extended. Even when the fingers can be flexed by the action of the flexor sublimis, the power of resisting passive extension is completely lost in the terminal phalanx of the two ulnar fingers. Paralysis of the *hypothenar* muscles abolishes lateral movements of the little finger, and diminishes the power of flexion at the proximal joint. Paralysis of the *interossei* and of the inner two *lumbricals* leads to the production of the "claw-hand."

The action of these muscles is to flex the fingers at the proximal joints with the distal joints extended. In the "claw-hand" the posture of the fingers is just the opposite of this, namely, extension at the proximal joint with flexion of the distal joints. Although all the *interossei* are paralysed, the defect is only seen in the ulnar fingers, as the radial *lumbricals* supplied by the median are still healthy. It is produced by the action of the long extensors, which being now unopposed, over-extend the proximal joints, and by the flexor sublimis, which flexes the second joint and draws the distal joint down with it. The clawing of the fingers is greatly accentuated when the nerve is paralysed below the point of origin of the fibres to the long flexors of the fingers. Other features of the "ulnar hand" are atrophy of the *interossei* and of the *hypothenar* eminence and persistent abduction of the little and ring fingers. The movements of abduction and adduction are lost in the inner two fingers, and often in the middle finger. Further, these fingers cannot be flexed at the distal joint, whilst the proximal joints are extended.

Paralysis of the *adductor pollicis* and of the inner head of the *flexor brevis pollicis* produces peculiar disturbances in prehensile movements. If the patient is asked to grasp a folded paper between his thumb and index finger, and to resist efforts to remove it by pulling, it will be found that this movement, which is normally very powerful, is grossly defective. He cannot grasp the object beneath the thumb with the second phalanx extended; but presses the tip of the flexed thumb against the outer margin of the index finger.

Sensory disturbances.—In complete lesions, all forms of sensation are abolished in the little finger, and along the ulnar border of the hand. Beyond this there is usually diminished sensibility on the ulnar side of the ring finger, and over a narrow area towards the centre of the hand on both aspects. Spontaneous pains are rare, and *vasomotor* changes are usually slight.

Partial paralysis.—In partial lesions the same symptoms are found in a less degree. The small muscles of the hand suffer most. Clawing may be slight or absent. Neuralgic pains may be felt in the distribution of the ulnar nerve; but *causalgia* is never seen in lesions of this nerve alone.

Recovery of sensation is usually complete before movement is regained.

The flexor carpi ulnaris recovers first, then the long flexors of the fingers, and last the small muscles of the hand. In these recovery is extremely slow. When recovery of movement is complete the patient can abduct and adduct the middle finger with the palm flat on a table, and he can also scratch the table with the nail of the little finger without moving his wrist.

THE MUSCULO-CUTANEOUS NERVE is derived from fibres arising from the fifth and sixth cervical nerves. It is rarely affected alone, but is often implicated with the brachial plexus. It supplies the biceps, coraco-brachialis and brachialis anticus. Flexion of the forearm can still be carried out by the supinator longus; but the power of flexion is greatly diminished. Sensation may be diminished or lost along the radial border of the forearm.

THE CIRCUMFLEX NERVE derives its fibres from the fifth and sixth cervical nerves. It supplies the deltoid and teres minor, and the skin over the deltoid. It may be injured alone in injuries to the shoulder and by pressure of a crutch. The chief symptom is paralysis of the deltoid with almost complete inability to raise the arm.

INTERNAL CUTANEOUS NERVE.—Division of this nerve produces a narrow area of anæsthesia on the inner side of the forearm.

THE LESSER INTERNAL CUTANEOUS supplies the skin on the inner aspect of the upper arm.

In war injuries lesions of the nerves of the lower limb are very frequent; but in civil practice, apart from sciatica, local lesions of these nerves are rare.

THE LUMBO-SACRAL PLEXUS.—The *lumbar plexus* is formed by the union of loops from the anterior branches of the first three lumbar nerves and a part of the fourth. The rest of the latter unites with the fifth to form the lumbo-sacral cord, and joins the sacral roots to form the *sacral plexus*.

The lumbar plexus may be damaged by abdominal tumours, and its roots by new-growth or other disease of the vertebræ. In a certain number of cases signs of inflammation of the lumbar plexus are found in association with sciatica or neuritis of the sacral plexus.

ANTERIOR CRURAL NERVE (L_2, L_3, L_4).—This is the largest branch of the lumbar plexus. It supplies the psoas, iliacus, pectineus, sartorius, adductor longus and quadriceps femoris. It may be injured alone by fractures of the pelvis or of the femur, by dislocations of the hip, or by implication in wounds, psoas abscesses or new growths.

The most prominent symptoms are loss of power to extend the knee, loss of the knee-jerk, wasting of the quadriceps, and sensory disturbances over the anterior surface of the thigh and inner surface of the leg. The psoas always escapes, unless the plexus itself is also damaged; but flexion at the hip may be imperfect through paralysis of the iliacus. Owing to the rapid dispersion of the branches in the thigh, wounds in this part often cause partial lesions. In these the nerve to the quadriceps is most often injured. The resulting paralysis causes serious disability in walking as the knee gives way at every step, especially in going down stairs, and lameness lasts for a long time after complete return of voluntary movement.

OBTURATOR NERVE (L_2, L_3, L_4).—This nerve is rarely damaged alone. It supplies the three adductor muscles, the obturator externus and the gracilis. The symptoms are weakness of adduction and internal rotation at the hip.

EXTERNAL CUTANEOUS NERVE (L_2, L_3).—This nerve supplies an area of skin on the buttock, and through its femoral branch the skin on the anterolateral aspect of the thigh. As a result of injury, but more often without obvious cause, the skin in the territory of this nerve may show peculiar sensory disturbances, which have been described under the name of *meralgia paræsthetica*. Most cases occur in men. In women it is usually associated with pregnancy. The nerve is tender on pressure at the point where it passes from under Poupert's ligament, and neuralgic pain or numbness and tingling is felt in the skin, which may be slightly insensitive on objective examination or extremely hyperæsthetic, so that the slightest touch causes pain. The symptoms, which are always unilateral, are made worse by walking and may cause serious incapacity by their persistence and severity. In severe cases the nerve should be excised.

The *sacral plexus* may be damaged by growths or inflammation in the pelvis, by compression during parturition, and by penetrating missiles. It is also often the seat of spontaneous neuritis.

THE GREAT SCIATIC NERVE (L^4, L^5, S^1, S^2).—This nerve supplies the flexors of the leg and all the muscles below the knee. It may be involved in pelvic new growths, or injured by fractures of the pelvis or femur. Next to the musculo-spiral it suffers in gunshot wounds more often than any other nerve.

Total paralysis.—The foot drops, and the toes point downwards. Walking is possible, but the patient cannot stand on the heel or toes of the paralysed foot. The knee is raised high, but the steppage is not so marked in total lesions as when the external popliteal alone is paralysed. All movement below the knee is abolished. When the wound is in the buttocks flexion of the knee is very weak. The foot becomes œdematous if allowed to hang down. Sweating is often absent on the sole and dorsum of the foot, but is normal on the inner side of the foot, which is supplied by the anterior crural. The skin is dry and thin, and may be scaly. Hyperkeratosis of the sole is common. Subjective sensibility is rarely affected. The skin is completely anæsthetic over the entire foot, except the inner border of the sole and around the internal malleolus. The anæsthesia extends upwards on the postero-external aspect of the calf in its lower two-thirds, embracing the tendo Achillis and external malleolus. Beyond this area of complete anæsthesia there is a wide zone in which sensibility is diminished. *The sense of position and passive movement is abolished in the foot and toes. The knee-jerk is present. The ankle-jerk is always lost. Stimulation of the sole may produce a contraction in the tensor of the fascia lata; but there is no response in the foot.*

Partial paralysis.—In wounds of the sciatic nerve it often happens that the fibres of the external popliteal alone are wounded, since the sciatic trunk often divides into the internal and external popliteal branches as high as the great sacro-sciatic notch. The symptoms are described below under paralysis of this nerve. In other cases, the fibres of the internal popliteal are damaged either alone, or with some of the fibres of the external popliteal. In this case the outstanding clinical feature is pain of the same nature as that already described in lesions of the median nerve.

EXTERNAL POPLITEAL NERVE.—This nerve may be injured as it winds

round the fibula by wounds or fractures or by compression of a tight bandage. The paralysis is usually severe, all the muscles being equally affected. The foot is dropped and inverted, and the toes are slightly flexed. Dorsal flexion of the foot, extension of the proximal phalanges of the toes, and abduction of the foot are impossible. The patient can walk, and he can stand on tip-toe, but he cannot run, and walking is made difficult by the foot-drop. Subjective sensory disturbances are usually absent. The skin is anæsthetic over a narrow band which extends from the outer surface of the leg in its middle third, downwards beside the outer border of the tibia, and along the middle of the dorsal aspect of the foot as far as the base of the toes. For an inch or so, on both sides of this band, the sensibility of the skin is diminished. The knee-jerk and ankle-jerk are present. The plantar response is always flexor. Vasomotor changes are slight, and trophic changes are absent.

INTERNAL POPLITEAL NERVE.—This nerve is rarely injured alone. It supplies the popliteus, the calf muscles, the flexors of the toes and the intrinsic muscles of the foot. When it is paralysed, the patient is unable to stand on tip-toe, or to extend or invert the ankle, or to flex his toes. Paralysis of the interossei leads to a claw-like deformity of the foot, associated with lowering of the heel and raising of the metatarsus—talipes calcaneo-valgus. The calf muscles are flabby and the ankle-jerk is abolished. Sensation is lost on the sole, except along its inner border, on the outer border of the foot, and on the plantar surface of the toes. Causalgia, similar to that in paralysis of the median, is very often present.

POSTERIOR TIBIAL NERVE.—This nerve may be injured by a penetrating missile or a deep wound in the calf. Movements of the ankle are unaffected, and anæsthesia is confined to the sole of the foot and heel, or merely to its inner half. The paralysis of the intrinsic muscles of the foot may escape detection, and the lesion may easily be overlooked, especially when the nerve is injured below the origin of branches supplying the flexor longus hallucis and the flexor longus digitorum. The symptoms then are pain in the sole of the foot, anæsthesia on the sole, and paralysis of the plantar muscles.

Treatment of Local Nerve Lesions.—Treatment must depend on the nature and degree of the lesion. During the long period which elapses between the onset of paralysis and the first signs of recovery, even in cases of simple physiological interruption of the nerves, every effort must be made to prevent degeneration of the muscles, to keep the circulation of the limb active, and to prevent the occurrence of contractures and deformities. Massage, movements, electrotherapy and suitable appliances all have their uses. With regard to operative treatment, it must be remembered that more than half the cases of nerve injuries undergo spontaneous cure. It is advisable, therefore, to wait three or four months before an operation is undertaken. If, at the end of this time, the wound is soundly healed and all signs of sepsis have disappeared, and if, as a result of repeated examinations, no sign of recovery has been detected, no harm can be done by exposing the nerve. If it is found to be divided completely, the ends should be "freshened" and sutured end to end. If the nerve is notched laterally, the edges of the notch should be pared and sutured, care being taken to preserve the bridge of uninjured tissue. Sometimes the nerve at the site of the lesion appears as a fibrous, flattened band between two swellings on the nerve. In most of

such cases the nerve is completely divided, and the condition calls for resection of this fibrous tissue and end-to-end suture. Another common finding, when the nerve is exposed, is a nodule or cicatricial swelling in the course of a nerve which has maintained its continuity. In these cases the continuity of the nerve should not be interrupted. It should be freed from adhesions, and incised in the long axis of the swelling. All operations which involve grafting of nerves are futile. For an account of the great advances in the technique of the surgical treatment of nerve injuries which have been made as a result of experience gained in the Great War, special treatises must be consulted.

The treatment of painful forms of nerve lesions is extremely difficult. In severe cases external applications and internal medication entirely fail. Simple freeing of the nerve sometimes gives relief. Where this fails, it may be advisable to practise complete division followed by immediate suture. Alcoholisation of the nerve trunk often gives immediate and lasting relief. Under general anaesthesia the nerve is freed, and then injected with 1 c.c. of weak alcohol at a point two or more centimetres above the lesion. This, of course, is followed by motor paralysis; but recovery occurs in about six months.

INTERSTITIAL NEURITIS

Synonym.—Neuro-fibrositis.

Definition.—A malady which commonly attacks the large nerve plexuses or nerve trunks, but which may affect any peripheral nerve trunk, and which is characterised anatomically by an inflammation of the connective tissues which surround and bind together the nerve fibres into the nerve trunks. This fibrositis, which may be local or diffuse in the affected nerves, is the result of the causes of fibrositis in general, and is frequently associated with fibrositis elsewhere, as, for example, when sciatica is associated with lumbago. The symptoms are those of irritation of the nerve fibres, namely, pain in the distribution of the nerve trunk, tenderness of the nerve trunk, muscular fibrillation and cramp. Loss of function of the nerve fibres in the way of loss of sensibility or muscular paralysis is the rarest of events in interstitial neuritis, and is seen only as the result of terminal cicatrization in severe cases. Muscular wasting is the rule, but it is a general wasting of muscles of the painful region, not confined to the distribution of the nerve involved, and therefore resembling the muscular wasting which is seen in joint disease.

Pathology.—The malady is met with soon after puberty, and is incident chiefly upon the first half of adult life, being unknown in childhood and rare in old age. It is often associated with other forms of fibrositis such as lumbago. Often it arises spontaneously, without external cause: but exposure to cold may directly cause it, as also may injury such as stretching, bruising or wounding of the nerve trunk. Gout and diabetes are well-known clinical associations.

The morbid anatomy is well seen when the nerve is exposed during operative procedures for the relief of the condition. The affected nerve trunk is swollen and pink in colour; the sheath is distended, and droplets of fluid exude when it is incised, and sometimes the nerve is adherent to the surrounding tissues. This inflammatory condition may be local and appear as a

pink bulbous enlargement of the nerve trunk, or it may spread widely over a long stretch of the nerve trunk and its branches. When the inflammatory process subsides there may be cicatrization of the peri- and endo-neurium. Only in the rarest cases does the morbid process become so severe as to interfere with the more important functions of the nerve trunk with the production of motor and sensory paralysis, and even in these cases complete ultimate recovery is the rule. The local inflammatory condition causes a slight shortening of the nerve trunk, and this causes the affected limb to be held in that position which will keep the nerve trunk most relaxed. It is also the cause of the severe pain which occurs on any movement which stretches the nerve trunk.

Interstitial neuritis is sometimes an associate of arthritis. For example, in arthritis of the shoulder-joint it is not uncommon to meet with definite involvement of the brachial nerves, and again in chronic arthritis of the hip-joint the inflammatory process may extend from the capsule of the hip-joint directly into the contiguous sciatic nerve.

The malady may affect any of the nerve roots or nerve trunks, and sometimes several of these may be co-involved. When the nerve roots are affected "radicular neuritis" results. The sciatic nerve is by far the most common seat of the disease, producing the condition known as "sciatica." Next in order of frequency come the brachial plexus, causing "brachial neuritis," the anterior crural nerve causing "anterior crural neuritis," the upper part of the cervical plexus producing "cervico-occipital neuritis," and the intercostal nerves producing the so-called "intercostal neuralgia."

Symptoms.—These are the same whatever nerve is affected, and consist in—(1) Pain radiating in the area of distribution of the affected nerve, of a dull, aching character with acute exacerbations and often very long lasting. (2) Tenderness of the affected nerve to pressure and stretching. (3) Subjective peripheral sensations such as tingling, burning or numbness. (4) General wasting of the muscles of the surrounding region with marked hypotonus, not confined to the muscles supplied by the affected nerve and akin to arthritic muscular atrophy. This wasting may reach a very remarkable degree. (5) Increase of the deep reflexes of the limb. (6) Diminution or loss of the deep reflex in the supply of the affected nerve. This is a valuable indication of the severity of the lesion. In a case of sciatica, for example, all the muscles of thigh and leg are wasted, the knee-jerk and the adductor-jerks are markedly brisk, whereas the ankle-jerk, which is in the sciatic supply, is diminished in slight cases and lost in severe cases. (7) The affected limb is held in a characteristic position to avoid stretching of the nerve, and the gait is similarly modified. (8) Trophic and vasomotor changes are not uncommon. (9) Fibrillation is often present.

Diagnosis.—There is sometimes considerable difficulty in the diagnosis of cases of interstitial neuritis on account of the almost identical clinical picture which may occur in the early stages of pressure upon nerve roots or nerves by tumours. The following points are of value in distinguishing the two conditions: The pain of pressure lesions is rarely so severe as that of interstitial neuritis. Tenderness on pressure or stretching of the nerve trunks is absent in pressure lesions. Signs of loss of function—paralysis and sensory loss—come on early in pressure lesions. The most

careful search should be made in every case for any possible cause for local pressure, such as primary and secondary neoplasms, spinal tumours, spinal caries and diabetes. To make a diagnosis of interstitial neuritis in the presence of a mammary or testicular carcinoma, removed or not, is to advocate the highly improbable, whatever the symptoms may be.

BRACHIAL NEURITIS.—This form of interstitial neuritis is somewhat rare, and is met with chiefly in women over the age of 35 years. Sometimes it follows injury to the brachial plexus from any violence causing undue separation of head and shoulder. More often it arises spontaneously. The pain, which is often of sudden onset, may be of great severity, and may be at first referred to the region of the plexus itself, the back of the scapula, the axilla, the forearm or the hand, is at first intermittent, but it soon becomes continuous and spreads over the whole upper limb. Tingling and numbness in the hand and trophic changes in the skin and nails of the fingers are the rule.

One of the great difficulties in this malady is that in the upright position the weight of the arm and shoulder carry the shoulder downwards and stretch the inflamed plexus, adding greatly to the pain. Therefore it should be treated with the recumbent position upon the back in bed. Further, every movement of the hand or arm tends to increase the pain. Splints which keep the arm in the abducted position and the shoulder raised so as to prevent tension upon the plexus are invaluable.

There is little difficulty in diagnosis, the only confusable conditions being arthritis of the shoulder and cervical rib, in neither of which conditions is there any tenderness of the nerve trunks of the plexus.

CERVICO-OCCIPITAL NEURITIS.—This condition, which is by no means rare, is characterised by pain in the upper part of one side of the neck, radiating over the branches of the upper cervical plexus, the great occipital being the most common and the supra-sternal, supra-clavicular and supra-acromial branches less common seats for the pain. The fibrositis not infrequently co-involves the fibrous structures in the region of the articular and transverse processes, giving rise to pain and stiffness of the neck on movement. When the pain is confined to the great occipital distribution alcohol injection is sometimes most efficacious.

SCIATICA.—This term is here confined to interstitial fibrositis of the sciatic nerve to the exclusion of every other variety of sciatic pain resulting from pressure on nerves or nerve roots or other lesions of the nervous system which have sometimes been included under the term "secondary sciatica." It has been said that true sciatica as here defined is never bilateral, and that bilateral sciatic pain is always the result of gross lesions involving the nerve. It is important that this error, which has crept into so many text-books, should be contradicted, for sciatica is not infrequently bilateral and the sciatica which occurs in glycosurics is usually bilateral.

The malady is not met with in childhood, but it begins to be common soon after puberty, and its incidence is greatest upon early middle life. In the majority of the cases it arises without assignable cause, sometimes injury to the nerve of any nature, as from a twist of the leg, a bruise or a fall is responsible. Only in rare cases does exposure to cold and wet seem to have excited the onset. It is important that the urine should be tested in every

case of sciatic pain, for glycosuria is more often found in cases of sciatica than is usually believed.

Symptoms.—The chief symptom is pain along the course of the nerve or of its branches, and since the sciatic nerve often divides within the pelvis into the great internal and external popliteal branches, the pain may be confined to the distribution of one of these alone. One feature of the pain valuable for diagnostic purposes is that it never reaches above the crest of the ilium, but in this connection it must be borne in mind that fibrositis of the back (lumbago) not infrequently precedes or accompanies the onset of sciatica. The pain may be partly intra-pelvic, for the sciatic nerve is formed within the pelvis. Where the interstitial neuritis is entirely intra-pelvic, tenderness of the nerve trunk to digital pressure fails as a physical sign. The onset is occasionally sudden, and associated with slight pyrexia and constitutional disturbances as in other forms of fibrositis: but, as a rule, the malady sets in gradually with pain in the buttock, back of the thigh or leg, in movements and in postures which make the nerve tense, or cause pressure upon it. The pain gradually increases in severity. It may be both gnawing and burning and sharp and darting in character. It is usually continuous, with occasional severe exacerbations which occur spontaneously or are excited by movement. Its intensity generally increases at night. The seat of the pain often varies from day to day.

Extreme tenderness of the nerve on pressure is rarely absent, except in those cases where the neuritis is intra-pelvic, and the tender region usually indicates the situation of the lesion of the nerve trunk. Stretching the nerve by extending the knee with the thigh flexed is productive of great pain which may be lasting. The best method of testing the sensitivity of the nerve to stretching is to put gentle pressure with the thumb on to the popliteal space as the patient sits in a chair with the knee bent at a right angle. Sometimes there is considerable tenderness of the muscles. The muscles waste not only in the sciatic supply, but throughout the whole lower limb and buttock, surely from reflex irritation as in arthritic atrophy. Cramp in the leg and reflex spasm are common, and muscular fibrillation is often seen. Paræsthesia in the form of tingling, burning and numbness is the rule; but loss of sensibility only occurs in the rarest and most severe cases, and its presence should always suggest the presence of a pressure lesion.

Peculiarities of stance, gait and position arise from the tenderness of the nerve to stretching, that position being assumed by the patient which keeps the nerve slackest. In standing, the weight of the body is placed upon the sound limb, and the other limb is flexed at hip and knee and extended at the ankle, with the toes only resting on the ground. In walking, the patient limps in this same position without straightening his knee or extending his ankle, and in bed he lies with knee flexed and ankle extended.

The knee-jerk is always markedly increased notwithstanding the wasting of the quadriceps, the only exception being when sciatica is complicated with anterior crural neuritis. The ankle-jerk being in the sciatic supply tends to be diminished in proportion to the severity of the neuritis, and in severe cases it is always lost.

Slight trophic and vasomotor changes in the periphery of the limb are commonly seen.

In very rare cases the cicatrisation which follows the inflammatory pro-

cess may cause motor and sensory paralysis of all the region below the knee. Such a case came under our care 2 years after the onset, and was explored by Sargent, who found the nerve in the gluteal region densely cicatrised and widely adherent to the muscles. The nerve was freed, and incised longitudinally in many places, and this patient made a complete recovery. Every degree of severity may be met with from the mildest to the most acute, and from the most rapid lasting but a few weeks to the most chronic lasting 2 or more years.

It is a most remarkable fact that severe sciatica never occurs twice in the same limb. One severe attack seems to free the affected nerve from subsequent liability to the affection, and it is comforting to be able to assure the patient that he will never have the trouble again in the same limb. In a very large experience we have never met with an exception to this rule.

Diagnosis.—Sciatica must be distinguished from other cause of sciatic pain. Arthritis of the hip is at once recognised by the limitation of joint movements. Disease of the sacro-iliac joint and ilium is distinguished by pelvic deformity and tenderness and by radiography. Pressure upon the nerve roots or trunks by neoplasms must be excluded by the most careful search for such growths in the spinal column, the pelvis, and in the course of the nerve, and generally throughout the body. A diagnosis of sciatica is almost certainly an error in any case in which a generalisable neoplasm is present or has been removed. Such pressure lesions producing sciatic pain soon produce motor and sensory paralysis, which is infinitely rare in sciatica, and, on the other hand, tenderness on pressure and on stretching, which is so conspicuous in sciatica, does not occur in the pressure lesions.

The pains of tabes and other nervous diseases when confined to the sciatic distribution are distinguished by the presence of other physical signs of those diseases.

Course and Prognosis.—Sciatica commencing acutely tends in the course of time to lessen in severity and become chronic, but some acute cases cure rapidly. When the malady has a slow commencement it usually lasts longer than does an acute case, and it is much more liable to exacerbations than when commencing acutely. The traumatic cases show no essential difference from the spontaneous, except that in the former adhesions of the nerve to the muscles from bruising is likely to prolong the duration of symptoms. The prognosis is always absolutely good as regards recovery, and in severe cases there is no likelihood of relapse. In slight cases, however, subsequent attacks are not uncommon.

Treatment.—The first essential in the treatment of all recent cases is to secure rest and to avoid all those things which excite or increase the pain. Sometimes the fixation of the limb in a semiflexed position by means of Liston's or Macintyre's splint gives great relief. The use of the bed-pan is advisable to avoid flexion of the hip and stretching or pressure upon the nerve in the act of defæcation. On the other hand, towards the end of a chronic case, active exercise with massage and passive movements are necessary to restore the shortening of the nerve. The application of heat in the form of hot-water bottles, poultices and radiant heat is invaluable for the relief of pain, and for curative purposes. Counter-irritation is very useful, and is best used in the form of the strong tincture of iodine which should be painted in a broad strip over the course of the sciatic nerve, from

sciatic notch to heel, daily until the skin becomes inflamed, just short of blistering. Massive injections of from 4 to 8 ounces of sterilised normal saline solution, made slowly into the region of the affected nerve at a temperature of 104° F., are often valuable both in acute and chronic cases. Massive injection of oxygen into the region of the affected nerve is a simple and harmless process which gives no pain and often brings most conspicuous relief. The injection is made direct from the cylinder by way of a thick piece of rubber tubing, a needle fitting and a hypodermic needle, until a considerable cushion of gas has been introduced. Acupuncture of the nerve with a series of specially designed needles is a useful and ancient remedy which acts by puncturing the sheath of the nerve, and allowing the escape of inflammatory exudation. Exposure of the nerve and incising the sheath by longitudinal incisions, and subsequently stretching it with the finger is a most proper method of treatment in acute recent cases where the pain is so severe as to prevent sleep for many nights, and where other palliative measures fail. This operation is often followed by immediate cure. It is not advisable in chronic and long-standing cases. Attempts to stretch the nerve by flexion of the thigh and extension of the knee may do great harm, and rarely do good. Among medicinal remedies, iodide of potassium has had a great reputation, but in our experience it is very disappointing. The salicylates are of great service, especially in the form of aspirin, which may be given liberally, and may be usefully combined with hexamine. Urodonal in doses of 1 drachm thrice daily is also often valuable. In the more chronic cases sulphur and guaiacum are serviceable. For the relief of pain heat is generally beneficial, but in some of the most acute cases the application of heat increases the pain, and in these an ice-bag will sometimes give great relief. All the analgesics of the coal-tar series, pyramidon, antifebrin, phenacetin, etc., are valuable adjuvants to relieve pain, and these may be conveniently prescribed with aspirin, or if sleep be difficult with barbitone or adalin. When pain is very severe and rebellious to the above-mentioned remedies, opium or morphine is indicated. It is essential from the exhausting quality of the pain that the patient should be well fed, and alcohol is often of service.

CERVICAL RIBS

Ætiology.—The development of the ribs at the thoracic inlet depends on the mode of formation of the brachial plexus, for the nerves are large and powerful structures in the embryo at a time when the ribs are soft and pliable. When the plexus is "normal" a well-formed first rib springs from the first dorsal vertebra. If, however, the plexus is "post-fixed," that is, when the contribution to the plexus from the fourth and fifth cervical segments is small and the fibres from the first and second dorsal segments form a powerful cord, this cord in rising over the first dorsal rib may compress and deform it to such an extent that it presents the characters of a rudimentary rib. On the other hand, and this is more frequent, when the plexus is pre-fixed, that is, when the contribution from the upper cervical segments is relatively large and that from the dorsal segments is small, a supernumerary rib is allowed to develop from the seventh cervical vertebra.

When this prefixation is pronounced, the seventh cervical rib is often very large and is easily felt in the neck. In these cases symptoms are usually absent. In a certain number of cases in which the abnormality is intermediate in degree, symptoms are caused by compression of the lower cord of the plexus as it passes over the supernumerary rib, or over the deformed first rib. This compression may be exercised by the bony portion of the extra rib, but more often the nerves are damaged by a fibrous prolongation of the rudimentary rib which connects it with the first rib.

But these abnormalities in the ribs only cause symptoms in some 10 per cent. of the cases in which they are present. Further, the symptoms are often unilateral with bilateral supernumerary ribs, and the symptoms are often most prominent on the side of the smaller extra rib. Again, the onset of symptoms is usually delayed until adult life is reached. It is clear, therefore, that some contributory cause must come into play. This is found in the dropping of the shoulder girdle, which is normal in adolescents, and is often excessive in persons whose muscular tone is low. In a child the clavicle rises boldly as it passes outwards. In a normal adult male the clavicle is almost horizontal, in women it droops slightly, and in those who develop symptoms of pressure on the nerves, the outer is usually distinctly lower than the inner end. In the latter, the lowest cord of the plexus is submitted to constant rubbing against the extra rib which rises and falls during respiration, and it is compressed by any movement of the arm which depresses the shoulder girdle. Relief is obtained by raising the shoulders, and patients soon learn to support the limb and to assume attitudes in which pressure on the nerves is relieved.

Women suffer most often, the right arm being affected more often than the left. The onset is usually gradual, but occasionally it comes on suddenly after childbirth, or on lifting a heavy weight.

Symptoms.—These may be sensory, motor, or vasomotor, either singly or in combination. Subjective sensory disturbances are most frequent. They take the form of numbness and tingling or neuralgic pains. Paræsthesiæ are most often unilateral, and are frequently confined to the ulnar or to the radial side of the hand and fingers. It is rare for all the fingers to be affected. Pain, when present, is usually felt below the elbow. It is often neuralgic, darting down the arm, and again confining itself to one border of the limb. It hardly ever radiates from the neck.

Objective sensory disturbances are usually slight or absent. They may be found over the ulnar or radial border of the distal portion of the limb in an indefinite area, which does not conform to the distribution either of the ulnar or radial nerve.

Muscular atrophy is not so frequent as sensory disturbance. In the "median type," wasting is confined at first to the abductor and opponens pollicis muscles, and the outer part of the thenar eminence shows a remarkable reduction in size, which contrasts strongly with the inner part, which retains its normal bulk. In the "ulnar type," wasting appears first in the small muscles of the hand supplied by the ulnar nerve. In some cases all the muscles of the hand and, to a less degree, the flexors in the forearm show considerable wasting. The atrophy is frequently bilateral and symmetrical.

Vasomotor disturbances are very common. The hands feel hot or cold,

they may be œdematous or discoloured, and the changes may suggest Raynaud's disease. Pressure on the subclavian artery sometimes causes inequality of the pulse. This disappears when the arm is raised.

Diagnosis.—The presence of pain, paræsthesiæ or vasomotor disturbances in the upper limbs, or wasting in the muscles of the hands, should always arouse the suspicion of supernumerary or rudimentary ribs. When pain is the only symptom, its distribution along one border of the arm or hand, and the patient's account of the manner in which it may be increased or diminished by raising the shoulder girdle or performing movements which depress it, usually direct attention to the cause. Symmetrical atrophy in the hands may suggest progressive muscular atrophy of spinal origin, but this diagnosis is usually rendered untenable by the association of sensory troubles or vasomotor phenomena, or by the findings on X-ray examination of the neck. For the differential diagnosis from syringomyelia, see page 1608.

Treatment.—Pain may be relieved by rest with the arms suitably supported. Atrophy calls for immediate operation to remove the offending rib. Pain is always relieved by operation, either immediately or after an interval of some months. The progress of atrophy is always retarded, and complete recovery may occur if an operation is undertaken early.

OBSTETRICAL PARALYSES

It is important and useful to group together under this heading all those conditions of paralysis occurring, either in mother or child, which are the result of the processes of labour in the passage of the foetal head through the pelvis. Autopsies upon the still-born and upon children who have survived birth for a few days only, have shown that hæmorrhage into the meninges is of common occurrence, and it has been argued that such meningeal hæmorrhages are the cause of many of the conditions of cerebral paralysis which are present immediately after birth, or which appear during the first year of life, and especially the cause of cerebral diplegia. The pathological conditions found in the brain in cases of cerebral diplegia, however, are such as make it absolutely impossible that they could be caused by meningeal hæmorrhage, for no sign of old hæmorrhage is ever found, nor could hæmorrhage cause a general cell atrophy of the brain without signs of any local lesion. It seems clear, then, that though meningeal hæmorrhage may be of common occurrence during birth, and may be the cause of still-birth, yet there is no clinical or pathological evidence to show that it gives rise to any lasting cerebral defect.

The following condition may occur: (1) In the child: facial paralysis; hemiplegia from laceration of the brain substance; fracture-dislocation of the spine with transverse lesion of the spinal cord; injury to the brachial plexus from the separation of head and shoulder in traction; and injury to peripheral nerve trunks at the elbow, axilla or groin, in using traction with the finger.

(2) In the mother: paralysis of the supply of the lumbo-sacral cord and obturator nerve from prolonged pressure of the head against the sacrum and pelvis.

Facial paralysis.—This is usually caused by the pressure of the forceps

upon the facial nerve as it crosses the ramus of the jaw, but it has been known to occur where instruments have not been used. When unilateral, as is the common event, it gives rise to little or no difficulty with sucking, and is evidenced by the unsightly deformity of the face, which is drawn over to the sound side. When bilateral, it is one of the causes of complete inability to suck, and on account of the flaccid symmetry of the face may easily be overlooked. It necessitates spoon feeding for a considerable time. Obstetrical facial paralysis invariably recovers within a few weeks and does not give rise to after-contraction. Gentle stretching and massage of the face with the finger is the only treatment required.

Hemiplegia from laceration of the brain may occur during delivery in contracted pelvis from the pressure upon the sacral promontory, and has been caused by the use of forceps. It is exceedingly rare, and is generally rapidly fatal from the associated hæmorrhage. It may occasionally be survived, with an irreparable hemiplegic condition.

Fracture-dislocation of the spine is produced by traction upon the after-coming head by pulling upon the trunk. We have seen it associated with injury to the brachial plexus. It occurs most often in the lower cervical region, and the transverse lesion of the spinal cord is usually complete.

Injury to the brachial plexus may occur in traction either upon the head, or upon the trunk, if the head is aftercoming, and is caused by an undue separation of head and shoulder on one side rupturing or straining the brachial plexus. The paralysis is usually of the upper arm or Erb type, the fifth and sixth roots being most affected, and the deltoid, biceps and supinator longus muscles being paralysed, but the whole plexus may be involved and even torn completely across. Traction upon a prolapsed arm has caused lower arm or Klumpke type of paralysis, in which the first dorsal and eighth cervical roots are most affected, and the intrinsic hand muscles and the flexors of the forearm are paralysed. The obstetrical lesions of the brachial plexus are for the most part serious lesions, many of the cases making no motor recovery at all, though sensibility is usually regained. The prognosis depends upon the severity of the damage to the plexus, as to whether the roots are actually torn or only bruised. The slight cases recover well enough.

Injury to the peripheral nerves from pressure or traction upon the flexures is seldom severe enough to prevent a rapid and complete recovery.

Paralysis of the lumbo-sacral cord and of the obturator nerves in the mother, immediately after parturition, is an exceedingly interesting clinical condition. In the first place, the lumbo-sacral cord is in a much more exposed position as regards the foetal head engaging the pelvis, than are the other nerves of the sacral plexus, and may be subjected to such severe pressure as causes paralysis, and in the second place, the obturator nerve actually crosses the brim of the pelvis and must of necessity be pressed upon by any large foetal head which passes the pelvic brim. The lumbo-sacral cord paralysis is evidenced by dropped foot and paralysis of the anterior tibial and peroneal muscles, and if it is severe, by loss of sensibility over the distribution of the fourth and fifth lumbar roots. Sometimes the third lumbar root area is affected. The obturator nerve involvement is shown by weakness or paralysis of the muscles supplied by the obturator nerve, namely, all the adductor muscles of the thigh. The paralysis may be noticed directly after parturi-

tion, or when the patient begins to get about upon her legs. The lumbosacral paralysis is usually unilateral, and is nearly always upon the right side. The obturator paralysis is not uncommonly bilateral, and both forms of the paralysis may coexist. There may be numbness, but no pain. This condition nearly always occurs with a first delivery, and often the child's head has been unduly large. It may recur with subsequent deliveries, but this is not a common event.

The prognosis is absolutely favourable, every case making a complete recovery in from a few weeks to a few months. The treatment is rest in the first place, with gentle massage and passive movements, and when power begins to return the patient may commence to get about.

POLYNEURITIS

Under the heading of peripheral or multiple neuritis, a group of maladies is described in which the main effect of the action of various noxious substances on the nervous system, is shown by symptoms pointing to injury of the peripheral motor and sensory nerves.

The more important of the many possible causes of peripheral neuritis may be classified as follows: (a) Metallic and organic poisons: *lead, arsenic, mercury; alcohol, carbon monoxide, bisulphide of carbon, aniline, dinitro-benzole.* (b) Poisons of infectious diseases: *diphtheria, influenza, dysentery, malaria, typhoid* and other acute fevers. (c) Disorders of metabolism: *diabetes, beri-beri.* (d) Cachectic conditions: tuberculosis, cancer. (e) Acute toxæmia of doubtful nature: acute infective polyneuritis.

A few cases have been described in which hæmatoporphyrinuria was a symptom. In some of these drugs of the sulphonal group had been taken, while in others the change in the urine seemed to be a result of chronic constipation.

In many cases no cause can be discovered.

The disease is characterised by the combination of flaccid paralysis and subjective and objective sensory disturbances of symmetrical distribution, mainly affecting the distal portions of the limbs. To a certain extent the symptoms vary with the nature of the poison at work. It is advisable, therefore, to give a separate description of some of the commoner forms.

LEAD NEURITIS

The effects of lead are confined almost entirely to motor neurons. Subjective sensory disturbances are often slight or absent, and in most instances there is no objective sensory loss.

Pathology.—The degenerative changes in the nerves are confined almost entirely to the motor fibres, and are most intense in the intramuscular twigs supplying muscles of the extensor groups. Normal and degenerated fibres are found side by side, the former becoming more numerous as the nerve is traced upwards. In cases of the Aran-Duchenne type, atrophy of the anterior horn cells has been found.

Symptoms.—In most cases of the common *antebrachial* or *wrist-drop type*, paralysis is limited to the extensor muscles of the fingers and wrists—that is, to the muscles supplied by the musculo-spiral nerve. But the supinator

longus and the extensor ossis metacarpi pollicis, also supplied by this nerve, usually escape. Inability to extend the first phalanges of the two middle fingers, owing to weakness of the common extensor, is usually the first difficulty. The special extensors of the index and little fingers, the long extensors of the thumb and the extensors of the wrist are next attacked, and the characteristic wrist-drop appears. As a rule the paralysis becomes severe about a week after it is first noticed. By this time it is usually bilateral and symmetrical, but for several days, or even for several weeks, it may be confined to one side. The affected muscles waste rapidly and the back of the forearm becomes flattened, thus rendering the intact supinator longus more prominent. In this form, loss of power always precedes atrophy, and some muscles may show weakness without any wasting. Recovery is almost always complete. Simple weakness without atrophy usually passes off in a few weeks. If the wasting is moderate and the muscles still react to faradism, recovery may be expected in a few months. When the atrophy is severe, a year or more may elapse before recovery is complete.

Occasionally the deltoid, biceps, brachialis anticus and supinator longus muscles are affected, either alone or in company with the forearm muscles—*upper arm or brachial type*. Less often paralysis occurs in the legs, the muscles supplied by the peroneal nerve, namely, the long extensors of the toes and the peronei being chiefly involved—*peroneal type*. Like the supinator longus in the arm, the tibialis anticus, although supplied by the peroneal nerve, usually escapes. This type is usually associated with paralysis of the forearm muscles, and runs the same course.

In the form of paralysis described above the features are those of a traumatic lesion to a nerve. Loss of power precedes, and may be more extensive than wasting, faradic irritability of the muscles is lost or diminished while the reaction to galvanism is retained, and recovery is usually complete. It is therefore called the degenerative form. In the second form, the paralysis has the characters of progressive muscular atrophy. Weakness and wasting come on together, faradic and galvanic irritability of the muscles are both diminished in proportion to the wasting, and the paralysis is often permanent. This is known as the primary atrophic form. It occurs especially in the small muscles of the hand—*Aran-Duchenne type*—but is sometimes irregular in its distribution and affects many muscles in all four limbs. It is often associated with the first form, but may occur alone. Wasting comes on slowly, and accompanies the loss of power, instead of succeeding it. It is much more intractable than the degenerative form, and often persists after muscles showing the first form of paralysis have recovered.

ARSENICAL NEURITIS

Peripheral neuritis may be caused by a single large dose of arsenic, or it may result from prolonged use of the drug in the treatment of such diseases as lymphadenoma, chorea and severe anæmia. It is a rare malady, and the likelihood of its appearing under the last-named conditions is negligible. It appeared in epidemic form in the North of England in 1900 as a result of the use of sulphuric acid containing arsenic in the process of brewing beer. The toxic action of arsenic with alcohol seemed to be greater than that of either alone.

Except that the mental condition is usually normal, the description given below of alcoholic neuritis applies to this form as well. Hyperæsthesia of the skin and tenderness of the muscles are more constant and more severe in the arsenical form, and paralysis and atrophy of the muscles are often more widespread and more rapid in their progress. Hyperkeratosis of the soles and pigmentation of the skin are characteristic of arsenical poisoning. In a suspected case, the diagnosis can be confirmed by the discovery of abnormal quantities of arsenic in the urine or in the hair and skin.

ALCOHOLIC NEURITIS

In former years alcoholism was perhaps the commonest cause of severe peripheral neuritis. At present it is a rare disease. It occurs most often in women, especially in those who take small amounts of alcohol frequently. It has often been the first indication of secret drinking.

Pathology.—The changes in the nerves are those of parenchymatous neuritis. They are most intense in the small branches supplying the skin and muscles, and they diminish in severity as the larger branches are approached. They are best seen in the terminal branches of the musculospiral and anterior tibial nerves. The wasted muscles often show a reduction in the size of their fibres, and an increase of connective tissue—fibrous myositis. The spinal cord may be healthy, but in almost all cases examination by modern methods shows changes in the nerve cells and degeneration in the tract fibres derived from the posterior roots.

Symptoms.—The onset is insidious, and in most cases premonitory symptoms, such as numbness and tingling in the extremities or cramps in the muscles of the lower limbs, are present for several months before actual weakness occurs. Subjective sensory troubles are a marked feature, even in the early stages. Besides numbness and tingling, the patients complain of feelings of excessive heat or of coldness in the limbs, or of severe aching or cutting pains in the legs. Painful cramp in the calf muscles is a common symptom. It is often worst at night, and may interfere seriously with sleep. Objective examination usually reveals sensory loss, in which the various elements of sensation are affected in a manner which is almost pathognomonic.

Stated briefly, there is anæsthesia of the skin with hyperæsthesia of the deeper structures. Light touches are not appreciated at all or many are missed, the temperature sense is defective, and the prick of a pin causes no pain, whereas even moderate compression of the muscles may cause the patient to cry out. The sensory loss is greatest in the feet and hands and diminishes towards the knees and elbows. Muscular tenderness is usually greatest in the calves. The soles of the feet are also unduly tender. Hyperalgesia is often well marked before anæsthesia of the skin appears. To the disability caused by pains and spasms, weakness of the muscles is added in all but the slightest cases. The arms may suffer first, but in most cases the extensors of the toes, the dorsiflexors of the ankle, and the extensors of the fingers and wrists are attacked in progression, and double foot-drop and wrist-drop result. To overcome the foot-drop, the knees are raised high in walking. This gives to the gait the "steppage" character which is common to all forms of peripheral neuritis. In most cases the distal flexor muscles are also affected,

but to a slighter degree. In severe cases, weakness extends to the proximal muscles and even to the muscles of the trunk. The affected muscles become soft and diminish rapidly in bulk. Unless precautions are taken, contractions occur in the flexor muscles and produce deformities of the limbs, which add greatly to the difficulties of treatment.

At the onset the knee-jerks are exaggerated, but in most cases by the time the patient comes under observation all the tendon reflexes are absent. The cutaneous reflexes may be unaltered, diminished or absent. Sphincter control is retained so long as the patient is fully conscious. Slight bilateral weakness of the face is often present but severe paralysis is rare. Ptosis, nystagmus, weakness of the external ocular muscles and even Argyll Robertson pupils, have been observed.

Trophic and vasomotor disturbances in the extremities are very common. The hands and feet often perspire freely, and they may be white and cold or red and hot. In some cases œdema of the hands or lower extremities is present. In chronic cases the skin of the hands and fingers is thin, smooth and shiny, and the nails are ridged and brittle.

In almost every case of alcoholic neuritis there is some *psychic defect*. One form—Korsakoff's psychosis—is characteristic of and almost peculiar to this disease. The most prominent feature is failure of memory and loss of appreciation of time and place. A patient who has been bedridden in a hospital for nervous diseases for several weeks, when visited by the resident physician who has attended her daily, will "recognise" him at once as Dr. X., whom she has not seen since he brought her first child into the world some years ago. She is now, she says, in a lying-in hospital which she entered yesterday, and has just been confined with her second baby, who is in bed beside her. She also "recognises" strangers at her bedside, and connects them with events of long ago. She went for a walk this morning along certain streets which she names. In her travels she met several old friends with whom she had conversations, which she repeats—and so on. Everything is related in the most circumstantial manner, and if the facts were not known her tale might well be accepted as truth. A clinical clerk has been known to take a long "history" without realising that it was entirely fictitious. In most cases the mental defects are not so gross. There is merely a failure of memory, to which is added moroseness and irritability, caused by withdrawal of alcohol.

DIPHThERITIC PARALYSIS

The toxins of diphtheria are highly obnoxious to nervous tissues, and some form of paralysis occurs in a very high proportion of the cases. The intensity of the paralysis bears no relation to the severity of the local infection, for cases, in which the original disease has passed unnoticed, may be followed by serious damage to the nervous system. The nervous manifestations of diphtheria fall into three distinct groups, namely, the local, the specific and the generalised paralyses.

Local paralysis occurs in parts related anatomically by nervous connections to the site of the diphtheritic lesion. In faucial diphtheria, the local palsy appears in the palate. In extra-faucial diphtheria, *e.g.* infected sores on the limbs, the local palsy appears in the muscles supplied by the segments

of the cord to which afferent nerves from the infected focus pass. The reason for this is, that toxins elaborated by the diphtheria bacillus ascend from the primary focus to the cord or the medulla, in the perineural lymphatic channels of the afferent nerves. Having reached the central structures, they diffuse to neighbouring motor cells and, by injuring them, cause paralysis of the muscles they supply. Paralysis of the palate therefore does not occur except in faucial diphtheria.

The *specific* manifestation of diphtheria is paralysis of accommodation. Like trismus in tetanus, it is not due to a local lesion, but occurs in many cases, whatever the site of origin of the toxins. It is present in cases of both faucial and extra-faucial diphtheria, and is most probably an effect of toxins circulating in the general blood stream.

The third or *generalised* form of diphtheritic paralysis is multiple neuritis. It follows extra-faucial as well as faucial diphtheria, and is also a result of the action of toxins circulating in the blood.

Pathology.—The pathological changes in the nervous system are in complete accord with the symptoms. In cases of faucial diphtheria with palatal palsy, acute degenerative changes are found in the nuclei of the medulla. As a rule, the peripheral fibres connecting the palate with the medulla appear healthy. This is accounted for by the peripheral situation of the perineural lymphatics, along which the toxins travel to reach the central structures. The nerves are further protected by their neurilemmal sheaths. In their intramedullary course, where this protection is absent, the fibres show degeneration of their myelin sheaths.

When the primary focus is on the trunk or limbs the same degenerative changes are found in the corresponding part of the cord. In these cases medullary lesions are absent. In multiple neuritis, the chief lesion is a parenchymatous degeneration in the peripheral portion of the nerves supplying the distal parts of the limbs.

Symptoms.—As faucial diphtheria is the commonest form, the most frequent nervous symptom is *paralysis of the soft palate*. It is shown by the nasal quality of the voice and by the regurgitation of fluids through the nose. As a rule, the weakness is bilateral and equal, but in some cases it is greater on the side on which the local lesion is more severe. It makes its appearance in most instances about the end of the second week, but may come on as early as the fourth day, and as late as the sixth week. The soft palate is relaxed, and its movement on phonation is diminished. The palate may be insensitive, and its reflex is often diminished or lost. Recovery usually occurs in a few weeks. In rare instances the muscles of the pharynx and the vocal cords are paralysed. Together with palatal palsy, it is common to find weakness and tenderness of the sternomastoid muscles and of the masseters. These are also local effects.

Paralysis of accommodation appears about the same time as the palatal palsy, perhaps a few days sooner. The reaction of the pupils to accommodation as well as to light, can almost always be obtained. The trouble is subjective, and is shown by defects of near vision—for example, by inability to read small print. Hypermetropes suffer great inconvenience. In myopes it may pass unnoticed. Paralysis of any of the extrinsic ocular muscles with strabismus and diplopia may occur, and this may be either nuclear or peripheral in type.

Multiple neuritis usually comes on two or three weeks after recovery from the throat infection. Its presence is often detected when patients begin to exert themselves during convalescence. Weakness and aching pains in the legs, unsteadiness in walking, clumsiness in performing fine movements with the hands, feelings of pins and needles in the extremities—all these are common early symptoms. Weakness affects in varying degree the muscles of the neck, trunk and limbs. It is generally slight in degree, greater in the lower than in the upper extremities, and greater in the extensor muscles than in the flexors. Marked local atrophy is uncommon. In severe cases, life may be endangered by paralysis of the intercostals and of the diaphragm, but fortunately one set of muscles has usually begun to recover before the other is seriously affected. The small muscles of the hands and feet and the muscles of the calves and forearms are almost always tender on pressure. They are soft and flabby, and often show a partial reaction of degeneration.

Sensory ataxy is almost always present, and is often severe when the paralysis is trivial. It causes the patient great inconvenience, as it interferes seriously with walking and with the finer movements of the hands. Objective examination reveals sensory impairment of the "glove-and-stock-ing" type. On the hands and feet, the loss to light tactile stimuli is often complete, pain and temperature being less affected. As the limb is ascended, sensation gradually becomes normal. Even when the sensibility of the skin is but little diminished, the sensations of position and of passive movement in the extremities are often seriously impaired, and the sense of vibration is often lost.

Compared with the symptoms already described, loss of the tendon reflexes is a late sign. In the early stages they are exaggerated, but are lost later in every case. Their return is often long delayed, and it is common to see patients months after recovery of normal power, in whom the knee-jerks are still absent. It is common also to find them absent many months after an attack of diphtheria in patients who give no history of nervous symptoms during the attack. The skin reflexes are usually retained, and stimulation of the sole gives a normal response. The external muscles of the eyeball are sometimes paralysed. The most common defect is weakness of the internal recti, which causes a slight divergent squint, like that of myopia.

Cardiac failure is a grave but uncommon complication. It is not yet decided whether it is attributable to paralysis of the vagus, or to degeneration of the heart muscle. Vasomotor paralyses and disturbances in the nutrition of the skin, which occur so often in other forms of peripheral neuritis, are never seen in diphtheria. In those that survive the attack, complete recovery from the nervous troubles always occurs.

DIABETIC NEURITIS

In many patients with glycosuria, symptoms are present which point to changes in the peripheral nerves, or in the fibres of the posterior roots. In many respects they resemble tabes rather than peripheral neuritis; but as the exact pathology is still unknown, it is convenient to describe them here.

Pathology.—Degenerative changes have been found in the peripheral

nerves in some cases, in others these were healthy, whilst the intramedullary portion of the posterior roots showed degeneration, similar to that found in tabes.

Symptoms.—In some cases the only symptom is neuralgic pain in the distribution of one or more peripheral nerves. This is commonest in the lower limbs, where it simulates sciatica, and sugar is found in the urine in the absence of any other sign of diabetes.

In severe cases of diabetes the knee-jerks and ankle-jerks are diminished or lost in more than half the cases. This may accompany subjective sensory troubles in the lower limbs, or it may appear as an isolated symptom. The muscles are very often tender and the vibration sense in the feet is frequently absent. To objective examination, the sensibility of the skin is usually intact. Perforating ulcers of the feet have been observed.

Diagnosis.—The diagnosis of multiple neuritis from other diseases rarely presents any difficulty. It is made from the combination of symmetrical flaccid paralysis with sensory loss of the “glove-and-stocking” type, and tenderness of the muscles and nerves, confined to or most intense in the distal parts of the limbs. When sensory disturbances and diminished tendon reflexes are prominent symptoms and muscular weakness is slight, tabes may be suggested, and the resemblance is still greater when ataxia is present. Difficulty usually arises when the distinction has to be made between tabes and alcoholic neuritis, in a patient who has courted both diseases. In most instances the diagnosis can be made from the nature and distribution of the sensory changes. The lightning pains of tabes cannot be mistaken by any one who is familiar with their peculiar characters. Anæsthesia of the extremities is common to both diseases, but diminished sensibility around the nose and across the chest is peculiar to tabes and is present in almost every case. In neuritis the calf muscles and nerve trunks are tender, whereas in tabes the sensibility of these structures is usually greatly diminished. Hyperæsthesia to touch and temperature, and great exaggeration of the abdominal reflexes, also suggest tabes. The presence of Argyll Robertson pupils or of optic atrophy, though in favour of tabes, is not decisive, as both have been found in chronic alcoholism.

Treatment.—The first essential in treatment is to remove the patient from the influence of the existing cause. In alcoholic cases, rigid precautions are necessary to prevent secret access to alcohol. To attain this, treatment in an institution is almost a necessity. In most instances when the cause, whatever it may be, is removed, gradual improvement sets in and complete recovery ensues, in a time that varies with the severity of the symptoms. During this time the physician's most important duty is to prevent the occurrence of deformities and contractures. From the beginning, each joint in the affected limbs should be moved passively to its full range several times each day, and care should be taken to ensure that the attitude of the limbs during rest is a suitable one, especially that the feet are maintained at right angles to the legs by the use of appropriate apparatus. Drawing up of the heel must be prevented at all costs.

Gentle massage is soothing in the acute stage. Later, more vigorous rubbing may be given, and the patient should be encouraged to move the limbs voluntarily. Electricity is of doubtful utility. Analgesic drugs and

soothing applications may be needed at the onset. Thereafter, local treatment to the limbs is combined with measures to improve the patient's general condition.

LANDRY'S PARALYSIS

In the year 1859 Landry applied the name "acute" to a case in which acute flaccid paralysis with loss of reflexes and without sensory disturbances commenced in the periphery of the lower limbs, and rapidly spread upwards. The arms were next involved, first in the periphery, and later the trunk, respiratory muscles, neck, and lastly the cranial muscles were involved, and death occurred from respiratory failure. He made a careful microscopic examination of the spinal cord with the methods then at his disposal, and failed to detect in it any morbid changes. He subsequently described this symptom complex, which has since borne his name, from an analysis of 10 cases.

Since this time a large number of cases have been recorded which from the acute nature of the onset, and from the spreading nature of the paralysis, have been described as cases of Landry's paralysis. This name should be restricted to those cases of acute spreading paralysis, in which disorders of sensibility and sphincter trouble are absent or little marked, and in which recovery is complete if the patient survives, and in which no gross lesion is found within the nervous system after death.

It is important to bear in mind the fact that acute spreading paralysis may be produced by gross lesions of the nervous system, and it is most important in diagnosis that these conditions should be at once distinguished from Landry's paralysis. Foremost among such conditions are acute spreading myelitis and hæmorrhage into the theca. These are at once distinguished by the simultaneous development of sensory, motor and sphincter paralysis, and thecal hæmorrhage is further distinguished by the results of the lumbar puncture.

Acute poliomyelitis may also, in rare cases, give rise to a spreading paralysis, and cause much difficulty in diagnosis; but it is invariable that some permanent paralysis remains upon recovery, and, further, the lesions of poliomyelitis are both gross and characteristic.

The majority of authors who have written upon this subject have made the attempt to separate Landry's paralysis from the group of "acute toxic polyneuritis," both on pathological and on clinical grounds. Such a separation would appear to be entirely unsupported by the evidence. For in Landry's disease we are certainly dealing with an acute toxic process which has an especial physiological selective capacity for the lower motor neurons, though its action is not always quite confined to them. Exactly the same holds good for the majority of the conditions, which are grouped together as "acute toxic polyneuritis." In both these conditions all the nervous pathological changes which have been discovered are confined to these lower neurons, motor and sensory, and are often in polyneuritis confined to the lower motor neurons. The assumption that has been made, that in Landry's paralysis the toxic process is incident upon the nerve cells in the spinal cord, whereas in polyneuritis it is upon the peripheral part of the neuron—the

periphery of the nerve fibre, does not rest upon any sure foundation, and is unsupported by any clinical or pathological facts. It is probable that, in all conditions of toxic polyneuritis, the poison acts upon the neuron as a whole, and that the devitalising action of the poison is first manifest at the extremities of the neuron, both centralwards and distalwards, and both physiologically and histologically. The clinical separation of Landry's paralysis and polyneuritis is equally artificial and impossible, though much stress has been laid upon the presence of disturbances of sensibility, and the strictly peripheral distribution of the paralysis in polyneuritis. As regards sensory disturbance, this clinical feature is dependent upon the peculiar selective capacity of the poison. For example, in many conditions of polyneuritis, sensory disturbances are conspicuous by their absence throughout, as in some cases of lead neuritis and diphtherial neuritis. Further, peripheral distribution is not even the rule in polyneuritis, and forms, in which the paralysis is as much or more proximal than peripheral in distribution, are frequently seen. Further, the now generally accepted advent of so many poisons to the nervous system by means of the perineural lymphatics, which deliver the dose locally into the nervous system to be subsequently spread within the nervous system, must necessarily render the conception of peripheral distribution as an essential in polyneuritis untenable. The following description of this malady is based upon the personal observation of 10 cases with 4 autopsies which have come under our observation at the National Hospital and at St. George's Hospital.

Ætiology.—What is known of the causation of the disease in general resembles very closely that of acute polyneuritis. It affects males much more frequently than females, and occurs chiefly in adult life between the ages of 16 and 54 years. The cases which have been reported in children were probably examples of the spreading type of poliomyelitis. In many cases the patient is taken ill in the midst of good health, while in others there has been some known cause productive of a toxic state, such as exposure to heat and cold, specific infections (of which small-pox, diphtheria, enteric fever, influenza and cellulitis are the most important), or a febrile attack of obscure nature. Still more frequently it has immediately followed upon symptoms indicative of gastro-intestinal toxæmia.

Pathology.—Slight hyperæmia of the spinal cord, and especially of the grey matter, with a few punctiform hæmorrhages, is the only change noticeable upon naked-eye examination. Very definite histological changes are found upon microscopic examination in the anterior horn cells and in the cells of Clarke's column, where any degree of change may be found, from an early pericentral chromatolysis to a complete loss of the chromatin granules and concentration of nuclei. Neuronophagia seems not to occur. The most intense changes are found in those regions corresponding with the first appearance of the paralysis. The myelin sheaths of the spinal cord often show a diffuse fatty change when examined by the Marchi method. No neuroglial proliferation occurs. The blood vessels are engorged, but are free from mural changes. The peripheral nerves show some degeneration, secondary to the affection of the cells. The skeletal muscles show early fatty changes. The whole of the changes found in the nervous system seem to be of a completely recoverable nature, and this is in line with the

almost invariable clinical outcome, that if the patient survives he recovers perfectly.

The cerebro-spinal fluid is in excess, and clear. In two of the cases under our care, it presented no abnormality either as regards cell or albumin content. In other cases there is an excess of albumin, and in this respect it resembles the cerebro-spinal fluid of polyneuritis, which is usually albuminous, and sometimes so highly so as to clot spontaneously. Enlargement of the spleen and of the mesenteric glands is not uncommonly found.

In 1903 Buzzard, in a very typical case which had been under our care, isolated a micrococcus in pure culture from the blood after death, and he found this same organism in the loose tissue forming the external layer of the theca. Injection of this organism into a rabbit by the subdural method produced, after some days, a rapidly spreading paralysis, and the same organism was found in the theca of the rabbit, and isolated in pure culture from its blood. The organism was not discovered in the spinal cord nor in the arachnoid space of either the patient or of the rabbit, and in neither case were there inflammatory reactions in these tissues.

Symptoms.—The onset is in some cases abrupt, with the appearance of the characteristic spreading paralysis. Much more frequently the paralysis is preceded by certain premonitory symptoms, which may last from a few hours to days or weeks. These symptoms may consist in malaise, headache, lassitude, insomnia, anorexia, constipation, gastralgia, vomiting and diarrhoea, and there is not infrequently slight elevation of temperature. More characteristic still among the prodromal signs are subjective disturbances of sensibility. Pains in the back and limbs are common, and may be of a dull aching nature, or they may be sharp and shooting in character. Numbness, tingling, "pins and needles" and other paræsthesias may occur over any part of the body, and are most commonly complained of in the periphery of the limbs. The muscles may be locally tender during this prodromal stage.

The paralysis usually comes on quickly and smoothly; but sometimes a cessation of its advance for a time is followed by a rapid exacerbation. Such an exacerbation proved fatal in one of our cases weeks after the onset, some considerable recovery having occurred during the interval. The paralysis is usually symmetrical in the end; but at its commencement, and in slight cases, which soon recover, there may be very considerable asymmetry of distribution.

As in Landry's original case, it is not uncommon for the paralysis to commence in the periphery of the lower extremities, to ascend rapidly, and to involve the muscles in the order of their innervation from the spinal cord, the trunk becoming affected before the upper extremities, and the intercostal muscles before the diaphragm. Such a true ascending paralysis must be due to direct spread of the toxic process within the spinal cord; but it is by no means usual in Landry's paralysis. For the muscular weakness may commence in any group of muscles, as, for example, in the face, neck, upper extremities or trunk, and when so commencing the spread of the paralysis is downwards, constituting a descending type of paralysis. The spread of the paralysis seems always to be in terms of the contiguous elements of the spinal cord.

In Landry's paralysis, as in acute polyneuritis, the innervation of the respiratory muscles seems to be peculiarly resistant to the toxin, for in both

these diseases we have seen cases completely recover, in which the paralysis was universal and complete for a time, with the exception of the respiratory muscles, which retained some activity sufficiently long to outlast the height of the paralysis.

It is not uncommon to see in Landry's paralysis and in acute polyneuritis, when the paralysis is widely spread and affecting trunk and limbs severely, that the paralysis seems to be proximal in distribution and that while no voluntary movement of any trunk muscle nor of any muscle of the proximal parts of the limbs can be called forth, yet feeble movements of fingers and toes may be possible. This has been a marked feature in every case of Landry's paralysis which we have examined, either during the onset or during the recovery. In this connection it must be remembered that this appearance may be simply a matter of gravity, and the amount of weight which the feeble muscles have to lift in their contraction. Lastly, there are a few cases in which the onset of the paralysis is not local, but is general and gradually deepening.

The paralysis is of the painless, flaccid type, and is associated with a complete abolition of the deep and superficial reflexes in the affected area. It first appeals to the patient as tiredness and heaviness in the affected region when commencing in the legs, trunk or shoulders, and as a loss of the finer movements when commencing in the hands. It usually takes some hours, and occasionally some days, to become complete. Generally it advances smoothly and regularly upon the regions previously unaffected, until the respiratory muscles and the muscles of the face and neck are affected, when it is the usual result for respiratory failure to prove fatal. Sometimes, however, the advance may cease for a while, to be followed by a more rapid advance of the paralysis.

In those cases which recover the advance of the paralysis ceases, and those muscles which have been most recently affected begin to show some recovery quickly. In one case, for example, which we watched through the night, with an advancing paralysis, the intercostal muscles failed completely, swallowing became difficult, and the facial muscles showed signs of increasing weakness. Then the diaphragm failed, and the patient was left breathing feebly with the sternomastoids and scaleni. After remaining about an hour in this apparently hopeless condition, it became obvious that the diaphragm had recommenced to act, and this was followed within a few hours by the intercostals, and within 24 hours the facial and bulbar paralysis had disappeared. This patient made a complete recovery within 3 months.

When the disease does not prove fatal either from respiratory failure, pulmonary complications or sudden syncope, the paralysis ceases to spread, and the patient enters upon the stage of recovery, which presents many features of interest. The flaccid muscles show a moderate degree of wasting within 2 or 3 weeks of the onset, this wasting being much less in those cases which recover rapidly. It is a general atrophy, and is not limited to particular groups of muscles. In rare cases, though fair power is regained, yet the muscles remain conspicuously small for life; but generally the muscles recover their bulk and tone completely. The paralysed muscles retain their excitability to faradism throughout, though there may be some slight diminution of faradic excitability in proportion to the general wasting of the muscles. Contractures and deformities do not occur.

Disorders of sensibility, though usually present in some degree, are completely overshadowed in intensity by the motor paralysis, which dominates the clinical picture of the disease. The paræsthesias, which have been described with the onset, often persist, and there may be cramp-like pains. Not uncommonly the muscles are tender upon deep pressure; but there is never that severe degree of tenderness met with in some forms of peripheral neuritis as, for example, in alcoholic neuritis. There is exceptionally blunting of sensibility, most marked in the periphery; but this is never deep, and is rapidly transient.

Though from the general weakness of the trunk muscles there may be some difficulty in emptying the bladder and rectum during the first few days and even retention with overflow incontinence that may require catheterisation from the same cause, yet these last but a few days, and there is never any true paralysis of the action of these sphincters. The deep and superficial reflexes disappear early with the onset of the first signs of the paralysis in the affected regions. The psychic functions remain entirely unimpaired throughout. Occasionally vomiting occurs, and it is difficult to explain. It is a sign of bad portent, and in one case under our care, which seemed otherwise hopeful, it was conspicuous throughout, and brought about a fatal issue.

Diagnosis.—The rapidly spreading character of the paralysis in Landry's disease is so striking as to necessitate distinction only from those few maladies in which a similar rapidly spreading paralysis may occur, and these are acute spreading myelitis, intrathecal hæmorrhage, acute poliomyelitis (spreading type) and acute polyn neuritis. Acute spreading myelitis is at once distinguished from Landry's paralysis by the severe sensory loss and sphincter paralysis, which in the former condition develop *pari-passu* with the motor paralysis and, further, if the myelitis does not involve the lumbo-sacral enlargement of the spinal cord, an extensor plantar reflex will be observed.

Similarly, thecal hæmorrhage is associated with severe sensory loss and sphincter disturbances. It is always an ascending paralysis, and the cauda equina and lowest regions of the spinal cord are first affected. The nature of this lesion should be at once revealed by the results of a lumbar puncture. The rare, spreading form of poliomyelitis presents more difficulty in diagnosis, especially in the acute stage. The general symptoms and the pyrexia are apt to be more severe in poliomyelitis. An onset in childhood is more suggestive of poliomyelitis than of Landry's paralysis. A fairly high polymorpho-nuclear leucocytosis in the blood, and a lymphocytosis in the cerebro-spinal fluid, are in favour of poliomyelitis. The persistence of local atrophic palsy on convalescence is absolute evidence of poliomyelitis. The distinction of Landry's paralysis from acute polyn neuritis is held by the writers of this article to be entirely artificial, since they argue that Landry's disease is merely a striking type of acute polyn neuritis.

Prognosis.—In about one-half of the cases the paralysis advances until the respiratory and bulbar muscles are involved, and death occurs from respiratory failure, usually on the third or fourth day, but sometimes not until 10 days or more have elapsed. In one case which came under our observation, after some degree of improvement in the paralysis had been noticeable, a rapid extension of the paralysis occurred in the sixth week, and proved fatal. So long as the paralysis is extending, and especially when

the respiratory and bulbar muscles are failing, the prognosis is very grave. The extension of the paralysis may, however, cease at any stage, and when this occurs the prognosis at once becomes favourable, even though there be considerable involvement of the respiratory and bulbar muscles. Any sign of improvement in the paralysis of the muscles last affected is of the most favourable import. The prognosis is best in those cases in which the paralysis nowhere becomes complete. When improvement has set in, it is almost invariable for the patient to make an uninterrupted and complete recovery in from a few weeks to 3 months.

Treatment.—The patient must be placed at complete rest, and the discomfort and panic which are likely to arise from the utter inability to move must be assiduously relieved by frequent changes of posture. The greatest care must be taken that the patient is adequately fed with nutritious and light food. Stimulants are usually indicated. A mercurial aperient should be administered early and the bowels regularly relieved, for in some cases obstinate constipation occurs. The bladder should be catheterised, if there is a difficulty in micturition. Both pain and pyrexia may be relieved by the administration of salicylates or aspirin.

Atropine seems to have a definite effect in checking the advance of the paralysis, especially when the respiratory muscles are weakening, and it further tends to check accumulation of secretion within the bronchi. Hexamine in 10-grain doses (0.6 gm.), 6 hourly, seems to be of some value. It may possibly act as a disinfectant to the respiratory and alimentary mucous surfaces, by which it is probable that the toxic agent gains access to the system. Oxygen may be administered where cyanosis occurs. Lumbar puncture should be performed daily, and the cerebro-spinal fluid removed freely on each occasion. When once the patient has shown signs that the malady has passed its height, and that recovery is commencing, little treatment is required except careful nursing and feeding. Gentle massage may then be employed.

MYOTONIA CONGENITA (THOMSEN'S DISEASE)

Definition.—A very rare malady, commencing in early childhood, which is hereditary and familial, and characterised by a striking slowness in the relaxation of the muscles after voluntary effort. The muscles pass into a spasm on voluntary contraction, which relaxes very slowly, resembling the contraction of the veratrinised frog's muscle, and its subsequent slow relaxation. Peculiar changes in the electrical excitability of the muscle and hypertrophy of the muscle fibres are constant.

Ætiology.—Beyond the facts that the malady is usually hereditary and familial, only a few sporadic cases occurring, and its incidence in early childhood, nothing is known of the causes. Cold, heat, fatigue and hunger conspicuously increase the symptoms.

Pathology.—The affected muscles are actually hypertrophied, and are always firmer to the feel than normal muscles, while sometimes they show a board-like hardness. The individual fibres show considerable hypertrophy, 75 per cent. of them showing, when measured, a diameter of from 60 to 145 μ against the 20 to 65 μ of normal muscle fibres. An increase of the muscle

nuclei also occurs. Dejerine and Sottas hold strongly that the disease is primary in the muscles. Gregor and Schilder deny this, on the grounds that the myogram obtained with the string galvanometer proves that its peculiarity cannot be of myogenic origin, but that the disorder is of central innervation.

Symptoms.—The presence of the disease first becomes evident from slowness, clumsiness and awkwardness of movement, with a great tendency to fall if the balance is upset. This is often most noticeable after rest, when, on attempting to move, the limbs seem glued down and move very slowly. Often the patient is able with exercise to work the stiffness off, and the myotonia lessens in the muscles which are being used; but if he is suddenly called upon to put another set of muscles into action, as, for example, by losing his balance, he is at once caught up by the myotonia and so is apt to fall. In other cases the myotonia increases or is uninfluenced by exertion. The muscles of the legs are as a rule most affected, but sometimes all the muscles of the body may be involved; while further, in a few cases the myotonic condition may be confined very locally to individual regions, as in myotonia atrophica. If the face be affected, when the patient smiles the smile will not relax for many seconds or even minutes; and when the upper limbs are affected, if the patient grips forcibly, he cannot disengage his hand for quite a while.

Passive movement does not reveal the presence of any rigidity except that following voluntary contraction. The abnormality affects the voluntary contractions and relaxations of the muscles only, and the peculiarities of these are—(1) their slowness, (2) their tonic character, and (3) the continuance of the contraction after voluntary impulses have ceased. The peculiarities of electrical excitability bear the name of the "myotonic reaction" of Erb. The contraction, either on faradic or galvanic stimulation, lasts much longer than the normal and relaxes very slowly, and this is more marked the stronger the current used; with the stable application of galvanism, slow wave-like contractions of the muscle are seen to proceed slowly from the cathode to the anode. There is no pain, no sensory disturbances or loss, and the sphincters and reflexes are unaffected.

Diagnosis.—The only malady which can be confused with Thomsen's disease is myotonia atrophica, in which the myotonic symptoms and signs are identical. In the latter malady, the onset is at a much later age, the incidence of the spasm is upon local groups of muscles, and the characteristic weakness of the facial muscles and atrophy of the sternomastoids, etc., at once distinguish it.

Course and Prognosis.—Thomsen's disease has no tendency to shorten and destroy life. It tends to become more marked from infancy to puberty, and then less marked again as age increases. It has never been cured.

Treatment.—This is entirely unavailing, except in the way of the avoidance of those conditions, such as fatigue, cold and hunger, which are known to increase the condition. Thomsen himself, who was afflicted with the disease, was always better with free exercise.

DYSTROPHIA MYOTONICA (MYOTONIA ATROPHICA)

Definition.—A disease of familial incidence, which begins usually in the third and fourth decades of life, and which is characterised by muscular atrophy of peculiar distribution and unlike that of any other disease. This atrophy occurs, first and most in the sterno-mastoids and facial muscles, next in the muscles of forearms, and may also be found in the muscles of mastication, in the vasti, and in the dorsiflexors of the feet and peronei. Associated with this wasting, but not commensurate with it, nor necessarily occurring in the same muscles, is a peculiar difficulty in relaxing the muscles after effort, called "myotonia," which gives to this malady an especial feature which at once separates it from all other forms of muscular atrophy. Signs of bodily dyscrasia are often present, the most important of which are cataract, premature baldness, atrophy of testicles, loss of sexual power and general bodily wasting. This disease was first placed upon a firm clinical basis by Batten and Gibb, and Steinert in 1909. Curschmann in 1912 adopted the term Dystrophia Myotonica as being more correctly descriptive.

Ætiology.—This condition is probably always familial, and the heredity is homologous—that is, it tends to appear in the same child-rank, in a number of apparently unconnected families at a common distance from one and the same ancestor, and often it seems to be entirely confined to one child-rank. The descent of the latent tendency is equally through the males and females, but where there is direct heredity the males more frequently transmit. The presence of the heredo-familial disease in earlier generations is often betrayed by other signs, such as cataract, frequent celibacy, childless marriages, high infant mortality, a dying out of certain branches of the family, a steady decline, generation after generation, in the family fortunes from affluence to poverty—all of which circumstances must be regarded as evidence that these families are in the grip of a progressive degenerative disease. The malady has been observed at the age of 10 years, but usually the onset occurs between the ages of 20 and 35 years. A large number of the patients have been unusually gifted and proficient in athletics prior to the onset. Both sexes may be affected. No exciting causal factors are known.

Pathology.—No definite changes have been found in the nervous system. The muscles presenting the myotonia have repeatedly been examined and found normal. In the atrophic muscles the morbid process singles out certain fibres especially, so that thick and thin fibres are found lying together. There is increase of the muscle nuclei round thick and thin fibres alike, though some atrophic fibres may be found with no increase of nuclei. Later, the nuclei tend to pass into the muscle fibres and become arranged in conspicuous rows, both in the centre of the fibres and underneath the sarcolemma. The muscle fibres become rounded, and thereafter the sarcoplasm dwindles and disappears, the columns of nuclei alone remaining to mark the spot from which the muscle fibre has departed. Changes in the anterior and middle lobes of the pituitary body, and in the cortex of the suprarenal bodies, have been found.

Symptoms.—The onset is gradual and the course extremely slow. The first symptom to call attention may be, either the difficulty in relaxing after

muscular effort—the clinging of the hand to the tool which has been grasped, the smile that is so slow to disappear—or the weakness and wasting of the muscles. The two chief signs of the disease—the myotonia and the wasting—seem to have no connection the one with the other, either as regards coincidence in time or place. The myotonia may appear years before there is any obvious wasting, and at least one case has occurred in which the patient was under the observation of a skilled neurologist, as a case of progressive muscular atrophy, for a year before any myotonia appeared. Moreover, the muscles which show the most conspicuous myotonia are often those which are not wasted, and finally those muscles which waste greatly tend to lose any sign of myotonia which they may have had. The extent and the intensity of the muscular atrophy and of the myotonia show great variations. The atrophy may be widely spread, and many muscles may be myotonic, or the former may be severe and the myotonia slight, or both may be present in minor degree only. Lastly, there are cases in which only the atrophy or only the myotonia is present. The myotonia consists in an inability to at once relax a muscle after it has been put into voluntary contraction, and the greater the effort used in contracting the muscle, the greater the difficulty with relaxation. The patient grasps one by the hand, and is unable to disengage the hand, but pulls it away still grasping, and it may take seconds to relax. He smiles quickly to a suitable stimulus, and the face remains fixed at the height of the smile for long after the emotion has vanished. In eating, his jaw becomes fixed, he is unable to perform any alternate movements in the muscles which are affected, but at a very slow rate. When the myotonia is severe and general, he is liable to fall like a log when walking, from inability to relax muscles which have been put into contraction. The myotonia is seen most often and to a greater extent in the flexor muscles of the forearm and in those of the face, but it may be quite general. In the same patient it may be very marked at one time and absent at another. The muscular weakness and wasting usually have a most typical distribution, involving the sterno-mastoids and other muscles of the neck, the facial and masticatory muscles—giving rise to the sad “myopathic” face, the vasti of the thighs, and the dorsiflexors of the feet, and this is the usual order in which the muscles are affected. It is always in one or other of these groups that the wasting commences, but sometimes the sequence of muscles attacked is quite different. From its place of commencement the atrophy may spread to all adjacent muscles, or it may pick out individual muscles at a distance. Fibrillation does not accompany the atrophy, and the weakness present is often much greater than the wasting will account for. The electrical reactions show a reduction both to faradic and to galvanic stimuli, with a tendency to a polar change. Some modification of the “myotonic reaction” is often superadded in those muscles which are wasted, and this usually is present in the muscles which are myotonic and are not wasted. This “myotonic reaction” consists in a very long, lasting contraction when the muscles are stimulated with every form of stimulus, and if the latter be strong it may last as long as 30 seconds.

The affection of the muscles of the face and jaw entails some alteration of articulation and phonation. The voice is low, it lacks intonation, and has a definite nasal quality. Sensibility is not affected.

The rule is for the muscle-jerks to be diminished or lost, and it is very

rare for all the jerks to be present in any case. When there is atrophy of the muscles concerned with a particular tendon reflex, this loss is easily explained. But often the deep reflex is lost in dystrophia myotonica, where there is no wasting of the muscles concerned, and the cause of this is to be sought in a pathological condition of the muscles.

Apart from symptoms and signs connected with the muscles, the most important sign of the dystrophy is cataract, which occurs in more than half of the cases. This cataract is often met with in otherwise healthy brothers and sisters of those who have the muscular changes, and in otherwise healthy members of earlier generations in the afflicted families. In succeeding generations after its first appearance, the age of occurrence of this cataract shows remarkable "anticipation"—that is, commencing at first as senile cataract, it appears at an earlier and earlier age with each successive generation, until with fully developed myotonia atrophica it appears in youth. The presenile cataract of the dystrophic generation begins as a star-shaped opacity, first in the posterior and later in the anterior cortical lamellæ, sometimes with fine point-like opacities scattered through the lens. It ripens quickly to a total soft cataract, with a small central nucleus.

The genital organs remain infantile in some cases; celibacy and childless marriages are common. More often sexuality is normal until the onset of definite symptoms, after which desire and power disappear. Early baldness is the rule. A general wasting of all the tissues of the body is seen in many cases. Ultimate atrophy of the testicles is usual.

Diagnosis.—There is no difficulty in the diagnosis when the distribution of the muscular atrophy is typical and when myotonia is obvious; it simply involves a recognition of the unique characteristics of the disease. When the myotonia precedes the wasting, the age of onset will distinguish this malady from Thomsen's disease, or myotonia congenita, and the oncoming of any sign of facial weakness or muscular wasting will make the diagnosis certain. When the myotonia does not appear until long after the wasting is apparent, the diagnosis is much more difficult. One has then to rely upon the peculiar distribution of the wasting, which is by no means invariable. Many authorities, however, are of opinion that some degree of myotonia is always the first sign to appear, and that scrupulous search for this sign in every case of muscular atrophy will lead to the certain recognition of all the cases of dystrophia. The untypical cases in which myotonia and muscular atrophy are absent or little marked are very difficult to recognise. Absence of the deep reflexes, otherwise unexplainable, should suggest the possibility of the presence of this disease, as also should loss of sexual power, and cataract should positively suggest the disease. The importance of repeated examination of the patient must be insisted on, since the myotonia, which is an all-important physical sign in the diagnosis, is apt to be variable.

Course and Prognosis.—This malady usually progresses very slowly, but occasionally very extensive and incapacitating wasting of muscles and weakness may develop within a year of the first symptom. Some cases seem to remain stationary for very long periods. The tenure of life is certainly short in all cases, and does not appear to be prolonged beyond the middle of the fifth decade. The oldest patient reported in the records as still living was aged 50 years.

Treatment.—There is no treatment known to benefit this disease specifically. Attention to the general health and to the well-being of the patient in providing such occupation as his capacity will allow, while avoiding fatigue, exposure to cold, and especially long confinement to bed, are the measures which are most likely to help. Neither electrical treatment nor massage has the slightest effect in altering the course of the disease.

JAMES COLLIER.

W. J. ADIE.

TETANY

Definition.—A group of symptoms of variable completeness and due to a multitude of widely different causes, characterised by a combination of intermitting painful cramp in the muscles usually of the extremities or larynx, but which may affect any of the voluntary muscles, with hyper-excitability of the neuro-muscular apparatus and peripheral sensory apparatus. It appears to be due to a disturbance in the calcium metabolism of the body, the withdrawal of calcium leaving the neuro-muscular apparatus in a condition of hyper-excitability. It can be produced experimentally in animals by calcium deprivation and by the removal of the parathyroid glands which control calcium metabolism, and when so produced it can be removed at will by the injection of a soluble salt of calcium into the circulation. Tetany has close ætiological and symptomatic relations with epilepsy, and may be hardly distinguishable from the tonic fits of epilepsy. It may occur also in typical form in any of the myotonias.

Pathology.—The researches of MacCullum and Voegtlin have shown that tetany is the constant sequel of parathyroidectomy and of calcium deprivation. The parathyroidectomised animals show: (a) a marked reduction in the calcium content of the blood and nervous tissues during tetany; (b) an increased calcium output in the urine and fæces during tetany; (c) an increased output of nitrogen and of ammonia in the urine with an increased ammonia ratio; (d) an increased amount of ammonia in the blood with evidences of some type of acid intoxication which does not disappear on the introduction of sodium salts. The injection of a solution of a salt of calcium into the circulation of the animal promptly checks all the symptoms and restores the animal to an apparently normal condition. The parathyroid secretion in some way controls the calcium exchange in the body. It is possible that in the absence of the parathyroid secretion substances arise which can combine with the calcium, abstract it from the tissues and cause its excretion, and that the parathyroid secretion prevents the formation of these substances. The calcium salts appear to have a moderating action upon the neuro-muscular tissues, and in their absence hyper-excitability and spasm occur. The mode of action of the parathyroid glands in this connection, the strictly local distribution of the spasm in some cases and the way in which many of the clinical factors of tetany produce the disease are at present entirely unexplained. Nor is it clear upon which part of the neuro-muscular apparatus the morbid process is incident. In herbivorous animals the parathyroid glands are entirely separated anatomically from the thyroid gland, and thus allow of exact experimentation. In carnivorous animals and in man the parathyroid glands are embedded in the lateral lobes of the thyroid gland, and the symptoms of parathyroid insufficiency, of which tetany is the

most obvious, are apt to arise when the lateral thyroid lobes are diseased or removed.

It would seem that parathyroid insufficiency may be brought about by a great variety of causes. In infantile tetany Yanase has frequently found hæmorrhages into the parathyroids. In the insufficiency tetanies from thyroid extirpation and disease the pathogeny is clear and the calcium treatment restorative. In acute epidemic tetany, thyroid involvements and therefore probably parathyroid involvements are known. Tumours, tuberculosis and many other pathological conditions of the thyroid gland have been reported in association with tetany. There seems to be some connection between tetany and myotonia, in that recurring tetany may pass over into myotonia. I have seen a case of myotonia in which painful spasm of the hands exactly resembling tetany occurred frequently.

Tetany may occur in simple acute forms and in chronic recurring forms. Its many etiological connections are well shown in the following classification after Frankl-Hochwart :

1. Infantile tetany which is usually associated with rickets or gastro-intestinal disorders, and of which laryngismus stridulus must be considered a local variety.

2. Tetany from over-exertion. A striking example of this rare condition came under my observation in a "girl guide," who though otherwise strong and healthy developed the most characteristic tetany when she had marched more than 6 miles.

3. Workman's tetany. This condition occurs epidemically as an acute recurring affection in the early spring in certain cities, notably Vienna and Heidelberg. It chiefly attacks handworkers such as shoemakers and tailors. The malady lasts from 2 to 3 weeks.

4. Gastro-intestinal tetany from pyloric stenosis, dilatation of the stomach, prolonged vomiting and diarrhoea, helminthiasis, etc. It is obvious that these conditions may profoundly modify both the calcium intake and excretion.

5. Tetany from acute infectious diseases. It has been known to occur in the course of typhoid fever, influenza, cholera, measles and scarlet fever.

6. Tetany from acute poisoning may be caused by chloroform, morphine, ergot, phosphorus, lead, and by renal and genital gland extracts.

7. Tetany of maternity may occur during pregnancy, following parturition or during lactation, especially when the latter is prolonged or the subject is weakly. (Nurse's Contracture.)

8. Parathyroid and thyroid tetany from gross disease or extirpation of these glands. It is sometimes met with in exophthalmic goitre.

9. Tetany has been rarely met with in the course of cerebral tumours, syringomyelia and other nervous diseases.

Symptoms.—In a well-defined attack of tetany four sets of symptoms are usually observable : (1) muscular spasms or cramps which may be followed by considerable weakness ; (2) Trousseau's phenomenon—pressure upon the nerves or vessels of a limb or encircling the limb will at once bring on or increase the spasm ; (3) Erb's symptom—hyper-excitability of the motor nerves to galvanism, the application of which often produces conspicuous fibrillation which may amount to a tetanus ; and (4) Chvostek's sign—there is great mechanical hyper-excitability of the motor nerves and muscles so that

when the facial nerve is lightly tapped as it crosses the jawbone, spasm of the whole of that side of the face occurs. In some cases one or more of the last three groups of symptoms may be absent. Occasionally there is marked tenderness of the sensory nerves with great hyper-excitability to galvanism—Hoffman's sign—and there may be oedema of the extremities, cyanosis, disturbances of respiration and of temperature and trophic changes in the skin, hair and nails.

Muscular cramps.—These may affect any muscles of the body, even the ocular muscles, and it is said also the bladder; but they are much most common in the periphery of the limbs, and especially of the upper limbs. The spasm is tonic and nearly always bilateral, and is usually induced by any mechanical or emotional stimulus, and in ratio to its degree it is very painful.

The small muscles of the hand are first affected. The thumb is crossed into the palm and the fingers drawn closely together, being flexed at the metacarpophalangeal joint and extended at the interphalangeal joints, so producing the "accoucheur's" or "penholding" position. The cramp may be limited to these muscles, or it may extend with marked flexion of the wrist and flexion of the elbows, and adduction at the shoulders may cross the arms over the chest. In rare cases the spasm closes the hand in a fist and may carry the arms away from the body so that they are held in the air.

In the lower extremities the toes and the feet are dropped and inturned, and there is usually flexion at the knee and hip with adduction. The legs are rarely affected so much as are the upper limbs, and frequently they escape altogether.

Spasm in any set of muscles in the body may be expected in tetany; but apart from those of the limbs it is rare. Trismus, risus sardonicus, laryngospasm and emprosthotonus or opisthotonus are occasionally met with, while spasm of the bladder, rectum, diaphragm and tongue muscles has been reported. In 7 of Frankl-Hochwart's 122 cases spasm of the eye muscles, sufficient to cause diplopia, occurred.

The attack of cramp lasts for a variable time, usually from 15 minutes to 3 hours; but it may last for 10 days and may prove fatal. The spasm is usually painful, and attempts to undo the contracture increase the pain severely. The spasm may abate and recur.

Laryngospasm is one of the common forms of local tetany, and occurs most often without spasm elsewhere. It is said to be peculiar to tetany of rachitic origin, and is commonly termed "laryngismus stridulus." It is met with in rickety children between the ages of 6 months and 3 years. The attack may come on at any time in the night or day—often when the child wakes or is startled—and it may recur with great frequency. Respiration is suddenly and quietly arrested by closure of the glottis; the air can leave the chest but cannot re-enter. The child struggles for breath, the face becomes congested or cyanosed. Then the spasm quickly relaxes, and as it does so air is drawn into the empty chest over the still closely approximated vocal cords with a high-pitched, crowing sound. Convulsions may occur during the asphyxial stage, and death may result before the laryngospasm relaxes.

Trousseau's phenomenon.—This is probably a reflex phenomenon due to irritation of the peripheral sensory nerves. Pressure upon the vessels or upon the nerves of the limb or encircling the limb will produce the spasm if absent, or augment it if present, in from 60 to 80 per cent. of the cases, and stretching

the nerves as in holding the arm vertically in the air has the same effect. That these performances upon one limb will evoke the spasm in the opposite limb proves clearly that the resulting temporary local anæmia is not the cause of the phenomenon.

Erb's phenomenon.—Hyper-excitability to the galvanic current is shown in both motor, sensory and special sense nerves, and fibrillation and spasm may be induced by cathodal stimulation of the muscles by currents which are sub-minimal to the normal subject.

Chvostek's sign.—Chvostek first pointed out the remarkable readiness with which ~~mechanical~~ stimulation induces spasm in the muscles in the tetany subject, and tapping of the facial nerve close to the lobe of the ear is a convenient method of eliciting this sign. Even stroking of the face may cause the spasm. It is interesting to note that this sign also has been met with in tuberculosis, chlorosis, gastro-enteritis, myxœdema and cretinism.

Diagnosis.—In a well-marked case this presents few difficulties, the peculiar nature of the spasm, its distribution, symmetrical with the hands most affected, and the characteristic appearance of the limbs when in spasm, with the Chvostek, Trousseau and Erb signs, suffice at once to determine the diagnosis.

Laryngospasm again is so characteristic as hardly to allow of error in its recognition.

~~Mild chronic tetanus~~, though presenting a superficial resemblance in the facial and jaw spasm, is distinguished by the frequently reflex nature of the spasm in tetanus.

~~Hysterical~~ spasm may closely simulate tetany, but there is usually associated sensory loss, the type of the spasm is different, and the attempts at voluntary movement and the emotional upset on passive movement are valuable in distinguishing hysteria. In tetania parathyreopriva the spasms may come on so rapidly and be so severe as to suggest epilepsy. In fact a case was recently sent into my ward at Queen Square Hospital with this diagnosis. Both lateral lobes of the thyroid gland had been removed for goitre. Consciousness was impaired at the onset of the attack, but the attack lasted many hours, and the patient was in agony from the painful cramp meanwhile.

Course and Prognosis.—In infantile tetany the course is invariably rapid to a favourable termination, a few cases fatal from laryngospasm excepted. For a few days the spasms may recur from time to time with lessening severity. The more severe and persistent cases are seen in older children, and in adults, where several attacks a day may occur for months. Here the course and prognosis are often determined by the cause and its removability. Epidemic tetany lasts but a few weeks, and that due to definite poisoning and to maternity comes to an end with the removal of the cause. There are, however, cases of adult tetany which, though benign at first, tend to become more severe with each recurring attack, and Frankl-Hochwart doubts whether these admit of cure. They tend to pass over into a grave form in which the attacks occur with greater and greater frequency and severity, and the patient dies as the direct result.

Treatment.—The treatment of tetany consists in the first place in the removal of any definite causes that may be present, such as rickets and intoxications, and in the second place by providing food rich in calcium such as eggs, milk or whey, and by administering calcium salts either orally or intra-

venously—calcium lactate and hypophosphite being suitable for the former, and calcium chloride, which has been extensively used in animal work, for the latter mode of administration. Parathyroid preparations are decidedly useful in all forms of tetany, and sometimes these seem more efficacious if thyroid extract is also given.

Transplantation of parathyroid gland has been so uniformly successful in animals that it is obviously applicable to cases of chronic tetany, and especially in tetania parathyreopriva.

Surgical interference is required in tetany from pyloric stenosis. Helminthiasis when present must be dealt with in the usual way. In laryngospasm a few grains of chloral hydrate will always avert the attacks until radical treatment is set going.

The pain caused by the cramp may be greatly alleviated by the application of cold to the affected limbs.

JAMES COLLIER.

MYASTHENIA GRAVIS

Definition.—A chronic malady of adult life characterised by—(1) a variable paralysis of muscles which is produced or rapidly increased by exertion, and which tends to disappear slowly during rest; (2) a permanent paralysis which shows no improvement with rest, and which succeeds the variable paralysis. This permanent paralysis may be very local in distribution, and may be associated with atrophy of the muscles; and (3) the affected muscles on strong faradisation soon cease to respond to faradism, but remain excitable by galvanism.

Ætiology.—The malady seems to be much more prevalent in England during the past 20 years than formerly. Rarely occurring before puberty, it commences most commonly in the third decade of life, and affects the sexes equally. Nothing is known of any causal factors either immediate or remote. The one clinical association which cannot be ignored is with exophthalmic goitre, for not only may myasthenia follow that malady, but the ophthalmoplegias which occur in Graves' disease bear no small resemblance to those of myasthenia. Senator states that a condition identical with myasthenia may occur in myeloma.

Pathology.—The only changes found within the nervous system are slight atrophy of those nerve cells which supply long paralysed muscles, and these changes are certainly not primary. In a certain number of the cases a large persistent thymus gland, showing proliferative and degenerative changes, or thymic rests showing similar changes, have been found. Small collections of round cells have been found repeatedly in the muscles and in other organs in all the cases, and they have been termed "lymphorrhages." They appear not to occur in other diseases. The limitation of the malady to the muscles, and the loss of faradic excitability with preservation of galvanic excitability, suggest a defect of the motor end organs such as is produced by the poison curare. The theory that the malady is due to the action of an endogenous toxin is difficult, because of the narrowly local affection of the muscles in some cases. For example, the eye muscles may be affected severely for 20 years, before any sign of myasthenia appears elsewhere.

Symptoms.—The first sign of myasthenia is the variable paralysis which may commence in any of the voluntary muscles. It may be unilateral at first, but soon becomes symmetrical. The paralysis appears first upon exertion and fatigue. The schoolmaster finds that towards the end of the day's work he cannot raise his arm readily to write upon the blackboard, or that his voice fails him in speaking. The housemaid finds that her broom slips in her hands, because of an ever-weakening grasp. The theatre-goer, towards the end of the performance, finds himself tilting his head farther and farther back to escape from an oncoming ptosis, or he develops diplopia. Next morning these symptoms are gone with the night's rest, to reappear with fresh exertion perhaps earlier each day, until work becomes impossible. The affected region may be narrowly confined, the eyes alone, the face, the muscles supplied by the trigeminus, or the larynx alone may be affected, or it may be the muscles of the upper extremities, or of the lower extremities, or of the back which may be solely involved. Lastly, the myasthenia may be quite universal, though never in the same degree in all the affected regions.

The incidence is greatest upon the muscles innervated from the brain stem, next upon the upper extremities and trunk, and least upon the legs. When the initial incidence of the malady is upon the eye muscles, diplopia and ptosis are the first symptoms. The paralysis is usually of the nuclear type, involving both eyes in terms of the conjugate movements; but inequality in the paralysis upon the two sides usually gives rise to decided strabismus and diplopia, and we have observed one case in which the initial paralysis was confined to one external rectus. When the permanent paralysis sets in, the axes usually become parallel, and the diplopia ceases. Until this event occurs, the great feature of myasthenic ocular paralysis is its variability, and its increase with fatigue. An ocular paralysis which is well each morning on waking, and which develops in the course of each day, is always due to myasthenia. The pupils are often unequal and sluggish in reaction, and the light reflex may be lost. Short, very quick, jerky movements of the eyes on attempted voluntary movements are often characteristic, and are quite different from the movements of nystagmus. Though ptosis is the rule, sometimes there is retraction of the lids, and both von Graefe's and Stellwag's sign may be present. Permanent nuclear ocular paralysis follows the variable paralysis in nearly every case, though it varies in degree. When the face is affected, epiphora, dysarthria and lack of facial expression with a peculiar weak "nasal smile" are conspicuous. The facies of myasthenia, with inability to close or pucker the eyes and mouth, the motionless and slightly dysarthric speech and peculiar smile are unmistakable.

Involvement of the muscles supplied by the fifth nerve causes trouble with mastication, and when the palate is affected there may be nasal speech and regurgitation of liquids. We have seen one case in which total unilateral paralysis of the larynx preceded the onset of typical symptoms by twelve months. When the tongue is affected it usually shows some wasting, especially of the linguales, and dysarthria results. Sometimes a widely spread involvement of this region causes severe dysphagia and dysarthria, and the former may be so great as to necessitate nasal feeding. The original name used for the disease, "asthenic bulbar paralysis," arose from this combination of symptoms. The permanent paralyses are rarely seen, except in the muscles supplied by the nuclei of the brain stem. The neck muscles

are usually affected when the malady extends on to the trunk, and it is a common thing to see the patients sitting at rest, either with the head supported by the hands, or resting upon the table. In the extremities the variable paralysis appears more marked at the proximal joints in most cases, and the test for myasthenia in the upper extremity is to ask the patient to extend his upper limbs level with the shoulder, when they will be seen to fall slowly down from the increasing fatigue paralysis.

Involvement of the respiratory muscles is common, and constitutes the gravest danger in the disease, since any effort, and especially an emotional outburst, may in a few seconds fatigue the respiratory muscles into a complete and fatal paralysis. Myasthenia often remains long confined to one region, and subsequently spreads rapidly. In two blacksmiths who were under our care the ocular paralysis began at the age of 18 years, and became complete within a year. These men continued their heavy work without further symptoms until the age of 42, when the myasthenia became general, and proved fatal within 3 months. Wasting of the muscles occurs only when there is marked permanent paralysis, and may be seen in the muscles of the tongue, face and in the masticatory muscles. In one fatal case under our care there was marked wasting of the intrinsic hand muscles on both sides.

The myasthenic reaction is only seen in those muscles which are showing conspicuous fatigue paralysis. If a strong interrupted faradic current is applied to such muscles, there is at first a strong contraction, but this is not maintained as in normal muscles, and it rapidly decreases until there is no response. If the stimulation is discontinued for a few minutes, and again applied, there is a further response, which tires more rapidly than the first. After exhaustion of the muscles by faradism, some volitional contraction remains. Exhaustion of the muscles does not occur from galvanic stimulation. Sensibility and sphincter control are not affected. The reflexes are normal in all but the rarest cases. Absence of knee-jerk has been met with, and the jaw-jerk is likely to fail when the trigeminal muscles are severely affected. The knee-jerk is not abolished when the quadriceps is exhausted, either by voluntary exertion or by faradisation.

Diagnosis.—This is never a matter of any difficulty if the variable paralysis, increasing with fatigue and lessening with rest, is conspicuous, for this phenomenon occurs in no other disease. When permanent paralysis only is present, the diagnosis requires care. It must be remembered that any unilateral or bilateral palsy of muscles supplied by the brain stem may be myasthenic. Here the history of a slow onset with variable paralysis and fatigue phenomena can nearly always be obtained, and the absence of the usual signs of gross lesions of the brain-stem nuclei, or progressive diseases affecting the latter, should avoid confusion. When, as sometimes happens, myasthenia begins with a unilateral ophthalmoplegia or laryngoplegia, the diagnosis may really be difficult. The possibility of such a commencement should be borne in mind, and a careful watch kept for the appearance of conclusive evidence. Other forms of nuclear ophthalmoplegia do not show a long history of variability and fatigue phenomena. Spastic and atrophic bulbar paralysis have distinctive features of their own, such as the spasticity of the former and the atrophy and fibrillation of the latter, and they do not show variability. Diphtherial bulbar paralysis and the bulbar paralysis of

tetanus have characteristic associations and signs. The bulbar paralysis of lethargic encephalitis shows little variability, and tends gradually to improve. The facial types of muscular dystrophy and myotonia atrophica show only a superficial resemblance to myasthenia in the facial appearance.

Course and Prognosis.—Myasthenia is always a very dangerous disease, as the term "gravis" implies. Some of the cases, and especially those in which the brain-stem region escapes, recover completely; but no records are as yet available to prove in what proportion of the cases this event occurs. The disease has proved fatal within a fortnight of the onset of symptoms, and, on the other hand, in our two cases here recorded, strenuous work was followed for 24 years after the development of permanent ophthalmoplegia. Improvement and relapses are very common. Frequently a patient will get rapidly worse, and become bedridden, in spite of careful treatment; to recover completely for the time being, when treatment has been abandoned as useless. Sometimes a patient with severe myasthenia will live for many years, if life be carefully protected. We have had one patient under observation in this state for 20 years, and she is not materially worse.

Sudden death is very liable to occur in any of the cases, but especially in those with bulbar paralysis and implication of the muscles of respiration. Death has been attributed to respiratory failure and asphyxia; but some of the patients die much too quickly for any such explanation. Two of our patients, seated at a table with their heads supported by their hands, and engaged in pleasant, quiet conversation, smiled, lowered their heads on to the table, and were dead without the slightest sign of distress or reaction, as if from sudden syncope.

Treatment.—The life should be so ordered as to eliminate all dangerous muscular fatigue. Beyond this there is little to do. Massage and electrical treatment are positively harmful. Tonics and hygienic measures may be of benefit. Strychnine and polyglandins do not seem to help. Mercury and iodide of potassium in moderate doses have seemed to me to be really of service in some of the cases.

FAMILIAL PERIODIC PARALYSIS

Definition.—A flaccid paralysis affecting the muscles of the trunk and of the extremities, associated with loss of the deep reflexes and diminution or loss of faradic excitability in the muscles. The paralysis is temporary in character, though it may be fatal during the attack, and it recurs at intervals. It is a rare malady, some 200 cases having been reported in the literature.

Ætiology.—It has been noted as early as the fifth year, and as late as the thirtieth year; but usually it appears about the age of puberty. Most of the cases occur in the male sex. Heredity is very marked, and the malady has been traced through five generations. Transmission may occur either through the male or through the female, and not infrequently a generation is skipped. Several members of the same family are usually affected.

Pathology.—Several cases have come to autopsy, but no lesion which could be associated with the symptoms was found. Biopsy of the muscles has given entirely negative results. From the severity of the symptoms, and

their complete recovery in very short spaces of time to complete health, the prevailing opinion as to the nature of the disease is that it is an auto-intoxication of a peculiar kind, associated with metabolic states, and induced by muscular activity, followed by a period of rest. There appears to be some evidence that the malady is associated with disturbance of gastro-intestinal and metabolic function. In Holtzapple's series of 17 patients, bulimnia preceded the attacks, and if the appetite was satisfied, and more particularly with rich and heavy foods, an attack was almost certain to follow in the night. Edsall examined the contents of the stomach during an attack, and found total in acidity, and that even starch digestion was not proceeding, showing that the whole digestive process was at a standstill. In a family with three members affected, which were under our observation, the incidence of the attacks seemed to depend entirely upon absence of food. If, for example, these patients dined at eight o'clock in the evening no attack occurred, but if, as their occupation of travelling merchants often determined, they dined very early or missed their evening meal, an attack occurred with certainty. It may be said that in these patients an attack could be produced at will by withholding food for more than a certain number of hours, and causing them to sleep in the starved state, and that the severity of the attack corresponded with the length of time of starvation.

Symptoms.—The clinical picture is so striking as to be almost dramatic. The patients are, as a rule, otherwise perfectly strong and healthy. In the family reported by Holtzapple alone, was migraine associated. The patient retires to bed feeling perfectly well, and awakens in the morning without pain or malaise, but with a flaccid motor paralysis, which always involves all four extremities, and which may reach all the muscles of the body, except those of the organs of speech, deglutition and respiration, and even these are often partially involved. Severe involvement of these vital muscles during an attack has caused death, as in six of Holtzapple's family, of eleven cases. The bladder and rectal functions are retained, and it is unusual for the patient either to void urine or fæces during the attack. The paralysis is usually at its height on waking; but it may subsequently increase. After lasting for a variable time, from a few hours to a few days, it passes off, sometimes gradually, sometimes rapidly. In the family under our care it was astonishing how the patients on waking in an attack could judge invariably how long the particular attack would last. They could judge with unflinching certainty when ability would return, and were in the habit of arranging their business accordingly. Most of the patients in addition to the severe attacks of paralysis suffer from what they call "morning weakness," temporary inability to grip with the hands, and slight disability with the feet on waking. It is curious that similar morning weakness, lasting a few minutes, is not very uncommon in normal children. The paralysis in periodic paralysis is flaccid, and there is loss or marked diminution of response to faradism during the paralysis. The deep and superficial reflexes are lost in the paralysed region. Objective sensation is not affected; but there may be subjective sensations of tingling and numbness, and the muscles may be a little sore and stiff after the attack. We have noticed flushing of the surface and sweating during the attacks. There is an invariable tendency for the attacks to diminish in frequency and severity after middle life is reached.

Diagnosis.—This must be evident to any one acquainted with the

symptoms of the disease. But there are other forms of periodic paralysis which bear more than a slight resemblance to the malady under consideration. For example, Rich described five members of his own family who developed transient recurring spastic paralysis of the face as the result of fatigue and exposure to cold, and we had two members of one family at the National Hospital in whom spastic paralysis of a severe type could be produced at will by withholding food and giving exercise.

Treatment.—When there is any definite cause for the attacks, such as dietetic considerations and fatigue, the obvious necessity is to adjust these to prevent the attacks. In our series of cases, where withholding food caused the attacks, the provision of an emergency food case, should ever they be put short on their journeys, caused the attacks practically to disappear. In Holtzapfel's cases, a dose of bromide over night seemed always to avert the attack; but in other cases this drug has not been efficacious. No treatment seems to alter the nature or duration of an attack, when once it has developed.

MUSCULAR DYSTROPHY; MYOPATHIC ATROPHY (THE MYOPATHIES)

Under this heading, a disease is described in which the voluntary muscles undergo primary degeneration, independent of detectable disease in other parts. To facilitate description, a number of clinical types have been distinguished according to the age at which the disease appears, to the group of muscles first attacked, to the presence or absence of pseudo-hypertrophy, or to the prominence of the hereditary factor. The chief of these are—(1) the pseudo-hypertrophic type; (2) the juvenile type of Erb; (3) the facio-scapulo-humeral type of Landouzy and Dejerine; (4) the distal type.

The first type is fairly constant, but there is in reality no sharp division between the different forms. That the others do not represent separate diseases is proved by the appearance of more than one of them in members of the same family. The disease is familial, and it is also hereditary in the sense that it may appear in some or all the members of a family through several generations.

The changes in the muscles in the myopathies are the same as those which occur when muscles degenerate from any other cause, namely, a slow and progressive atrophy of the contractile elements, with a concurrent increase of fat and fibrous tissue. In the pseudo-hypertrophic form the connective-tissue hyperplasia is excessive in some of the affected muscles and their bulk is increased. In the other forms of the disease, and in those muscles in the pseudo-hypertrophic form which become weak without any increase in size, the overgrowth of connective tissue may balance the loss of bulk due to atrophy of the contractile tissues, and the diseased muscles retain their normal size; or atrophy may proceed faster than hyperplasia, and the muscles waste from the beginning.

PSEUDO-HYPERTROPHIC PARALYSIS

Ætiology.—The cause of the disease is unknown. In many instances no antecedent cases can be traced in the family. In others, a family history

is obtained, always on the mother's side. Isolated cases occur, but more often several children are attacked in each generation. Boys suffer more frequently than girls in a proportion of about 5 to 1. Sometimes one sex alone suffers, sometimes both. It is rare for all the children to be attacked. The males who escape beget healthy children, whilst the females, who appear to have escaped, may transmit the disease to some of their offspring.

Symptoms.—The symptoms appear in early childhood. The onset is often delayed to the fourth or fifth year, rarely until towards puberty, and very rarely until as late as the twentieth year. In cases of late onset, enlargement of the calves has usually been present for many years. Weakness appears first in the muscles of the pelvic girdle. The child, who usually looks fat and strong, begins to walk late, he falls easily, and rises again with difficulty. He does not romp as other children do. He cannot skip or jump, and he has great difficulty in mounting stairs. At first the muscles may be normal in size, but, as a rule, some show obvious enlargement before the fifth year is reached. The enlargement is most conspicuous in the calves, the buttocks and the infraspinati. The erector spinæ, the quadriceps in whole or part, the deltoid, the supraspinatus and the triceps often show considerable hypertrophy. Occasionally the masseters are enlarged. At the same time other groups of muscles atrophy. This is most severe and most frequent in the latissimus dorsi and in the lower part of the pectoralis major. Later it extends to other muscles, and ultimately to those which were at first hypertrophied. The neck and face are spared. There is no exact correlation between the size of the diseased muscles and their power, but weakness is usually greatest in those which show most atrophy. The defects are greater in the proximal muscles, and diminish distally. The hands often retain good power to the end. This distribution of paralysis gives rise to certain characteristic defects of attitude and movement.

In standing the legs are placed far apart, and the upper part of the trunk is thrown back, so that a plumb-line from the most prominent vertebra falls behind the sacrum. This attitude compensates for the forward tilting of the pelvis, resulting from weakness of the glutei, which normally raise the anterior border of the pelvis by lowering its posterior border. In the sitting posture the lordosis disappears, for now the attachments of the flexors of the hip are approximated, and these muscles no longer lower the anterior border of the pelvis. On lying down the lordosis appears again, but can be abolished by relaxing the flexors of the hip-joint, that is, by flexing the hips passively. In walking, the feet are widely separated, and to clear the ground with the advancing foot the body is inclined first to one side and then to the other. This "waddling" produces a gait like that seen in congenital dislocation of the hip. The early preponderance of weakness in the extensors of the hip and knee is betrayed by the great difficulty experienced in mounting stairs.

The manner in which the child rises from the supine to the erect position is almost pathognomonic of the disease. He first tries to sit up, but fails. He then rolls over on his belly, and raises himself first on his knees and elbows, and then on his hands and feet. Next he places his hands on his knees, and as it is impossible for him to raise the trunk actively owing to weakness of the extensors of the hip, he literally climbs up his thighs, pushing the trunk passively almost to the erect position. The remaining power in the extensors may be enough to enable him to complete the movement.

If not, he jerks the shoulders back suddenly and gains the erect posture by a writhing movement, whose details are difficult to follow. To climb the thighs successfully a certain amount of power is necessary to hold the knees slightly flexed. When this power is lost he is no longer able to rise. The arms are also used to assist the weak legs in sitting down and in getting up from a chair.

As time goes on the weakness increases, and invades all the muscles of the trunk and limbs. Some of the muscles become shortened, and distortions are produced by permanent alterations in the position of the joints. The knees and elbows become flexed, the feet take up the attitude of talipes equinus, the spine becomes curved, and the whole body is grossly deformed.

The deep reflexes and the electrical excitability of the muscles diminish gradually as the wasting increases. Sensation is unaffected. The sphincters are not involved. The mental condition shows no abnormality.

Diagnosis.—The diagnosis is usually simple if a few of the outstanding features of the disease are known. The defects of attitude and movement, especially the mode of rising from the supine position, together with the characteristic association of enlargement of the infraspinati and calves with atrophy of the latissimus dorsi, form an unmistakable combination.

Prognosis.—This is most grave. Few patients reach adult life, and most die within 10 years of the onset of the disease.

Treatment.—Drugs have no beneficial influence. Massage and passive movement are useful in the prevention of contractures, and the efficiency of the muscles may be prolonged by suitable exercises. Walking should be practised daily, until it becomes impossible. Very often this is lost owing to contractions of the calf muscles, and is regained after tenotomy.

OTHER TYPES OF MYOPATHY

Ætiology.—The separation of the remaining types of myopathy from the pseudo-hypertrophic form is not an absolute one, as isolated cases are occasionally met with which seem to form a connecting link between the several varieties. The varieties, however, are habitually separate in occurrence, and in families in which numerous cases conforming to the types to be described hereunder have occurred throughout several generations, no cases presented the peculiar features of the pseudo-hypertrophic form. Moreover, the sex incidence as well as the period of onset is different in the two varieties, and it is possible that there is some essential pathological difference between them, and that they are separate diseases. With regard to the types of myopathy unassociated with pseudo-hypertrophy, no doubt exists as to their fundamental unity. They are merely varieties of one disease.

The influence of heredity is much more prominent than in the pseudo-hypertrophic form. Isolated cases occur, but they are rare. In most instances several members of a family are affected in the same and in succeeding generations.

The sexes suffer equally. The time of onset varies within wide limits—from infancy to old age. When the wasting begins in the face (*facio-scapulo-humeral type*) the disease frequently begins in childhood; but sometimes it begins there late in life. In the cases where it is first noticed in the muscles of the shoulder and pelvic girdle the onset is most frequent between the ages

of 15 and 35 (*Erb's juvenile type*); but here, again, it may begin in childhood or early old age, and the term juvenile is hardly applicable to it. The same variations in the age of onset are noticeable in cases where the atrophy begins in the forearms and legs (*distal type*).

The various types may be exemplified in members of the same family, and in the same family the age of onset may show extreme variation.

The cause of the disease is quite unknown.

Symptoms.—In the so-called juvenile form weakness and wasting come on simultaneously. In most cases they are first noticed in the arms; but in some families the legs suffer first. Of the arm muscles the biceps, triceps, and supinator longus are most often first affected. The lower part of the pectoralis major, the latissimus dorsi, trapezius and rhomboids are attacked in most cases. Atrophy of the serratus magnus is common; but it may escape even in severe cases. The deltoid, supraspinatus, infraspinatus and subscapularis usually escape. Atrophy of the forearm and hand muscles is rare.

In the legs, the flexors of the hip, the extensors of the knee and the glutei are most frequently affected. The muscles below the knee often escape entirely.

In the face the zygomatic muscles and the orbicularis are attacked. The face is dull and expressionless, the naso-labial fold is obliterated, the lips are habitually separated and the lower lip projects—myopathic facies. The face does not light up in conversation, in blinking the eyes are incompletely closed, and the articulation of labial consonants is defective. In smiling the mouth forms a straight line, instead of its angles being drawn upwards and outwards by the zygomatici. The power of whistling is lost. When the patient closes his eyes, or compresses his lips as forcibly as he can, they can be forced open with great ease. The buccinators are often affected, the tongue and the masticatory muscles never. The spinal muscles often atrophy, and in a few cases the abdominal muscles have been involved. The excitability of the muscles to faradic and galvanic stimulation usually diminishes in proportion to the wasting. The muscles never show fibrillary tremors. Sensibility is unaffected, and all the other functions of the nervous system are normal. Deformities are neither so common nor so severe as in the pseudo-hypertrophic form.

Diagnosis.—When a family history of atrophy is obtained, myotonia atrophica and peroneal muscular atrophy must be excluded. Myotonia atrophica is distinguished by the peculiar prolonged response of some of the muscles to voluntary, electrical and mechanical stimulation, and by the distribution of the wasting. Atrophy of the sternomastoids, which is constant and severe in myotonia atrophica, is never seen in the forms of myopathy now under consideration. In peroneal muscular atrophy the combination of atrophy in the lower limbs and small muscles of the hands, together with sensory disturbances in the lower limbs, is distinctive. In an early case, when the hand muscles are still normal and sensory changes are absent, the differentiation from myopathy may be impossible for a time.

In isolated cases myopathy is suggested by the appearance of muscular atrophy in childhood or youth. The diagnosis of myopathy is based on the distribution of the wasting in the absence of any sign of disease of the nervous system.

Prognosis.—The disease shows wide variations in its course and duration. The atrophy may remain confined to the group of muscles in which it begins, or extension may take place after an interval of several years. It rarely extends beyond the muscles mentioned above. In most cases, even in those that begin in childhood, progress is extremely slow, and as no symptom of the disease is necessarily fatal, death usually results from other maladies unconnected with the disease.

Treatment.—Owing to the variable course of the disease, it is impossible to estimate the value of any treatment that may be employed. Massage, electrical stimulation, and especially voluntary exercises designed to bring the weakened muscles into play, seem sometimes to retard the progress of the disease.

AMYOTONIA CONGENITA

Synonym.—Oppenheim's Disease.

Definition.—A malady of early childhood, usually congenital and sometimes familial, characterised by extreme flaccidity, smallness and weakness of the muscles, which are not actually paralysed, by lowering of the faradic excitability of the muscles, by loss of the tendon jerks, and by contractures in the region affected.

Ætiology.—In most cases the disease is present at the time of birth; in a few cases it has appeared during the first year of life in an apparently healthy child, and sometimes following an acute illness, such as bronchitis or diarrhœa. Usually sporadic, it has occurred in several children of the same parents.

Pathology.—The chief morbid changes are found in the muscles. In these very conspicuous pathological conditions are present, closely resembling those found in the myopathies. The three most striking conditions are—(1) the minute size of the majority of the muscle fibres, from $7\ \mu$ to $12\ \mu$; (2) the presence of a few very large or "giant" fibres reaching $140\ \mu$ in diameter, and larger than any fibre occurring in normal muscle; (3) marked regressive changes are seen in the giant fibres. There is increase of the connective tissue between the muscle bundles and a notable determination of fat. Reduction in numbers of the ventral horn cells of the spinal cord occurs, and the ventral roots are small and poorly myelinated.

Symptoms.—The extreme flaccidity of the affected muscles is noticed from the time of birth. They are small and weak, and though there is no muscular wasting and no absolute paralysis, yet in many cases the limbs cannot be raised against the action of gravity, nor can the head be held up. The great relaxation of the muscles and ligaments allows of the most fantastic attitudes being assumed without pain. When the child gets older, he is unable to sit up, but when placed in the sitting position the spine bunches up from absence of any muscular support, and he is unable to support his weight upon the weak legs. The amyotonia is symmetrical, and affects the legs always, the trunk often, the arms not infrequently, but never the face. Notwithstanding the flaccidity, some degree of flexor contracture is usually present. The faradic excitability of the muscles is much lowered, but not lost. Sensibility and the sphincters are not affected. The superficial reflexes are normal, but the deep reflexes are invariably absent in the affected

regions. The children are usually intelligent, with good bodily development, and growth proceeds normally.

Diagnosis.—This presents no difficulty on account of the presence of the flaccidity at birth, the absence of the deep reflexes, and the tendency slowly to improve. It has to be separated from those maladies to which it bears a superficial resemblance, namely, the myopathies, rickety weakness, obstetrical, infantile and diphtherial palsies.

~~**Course and Prognosis.**~~—Some of the children succumb during the early and severe stages of the disease, but the tendency of the disease is to improve slowly in the course of years, and in some cases almost complete recovery with return of the knee-jerks occurs.

Treatment.—This consists in aiding the natural tendency to improve with massage, passive movements and exercises, in treating contractures with tenotomy, and in attending to the general health and nutrition.

JAMES COLLIER.
W. J. ADIE.

SECTION XX

PSYCHOLOGICAL MEDICINE

PROLEGOMENA

THE isolation of psychiatry from general medicine was long and complete. In Greek medicine the treatment of mental disorder fell to the physician, but for many centuries, throughout the Middle Ages and far into the Renaissance, the insane person was regarded as possessed or bewitched, treated with exorcism or disciplinary measures of great severity and, loaded with chains, was confined as a criminal with criminals. Little by little, these barbaric practices were mitigated, and the physician again took the place of the jailer. Still, however, there linger in popular and even in official thought such notions as the necessity for "locking up" the lunatic, "bringing him to his senses," "keeping him under restraint," and not allowing him to "escape," while the idea of the mentally disordered person as a patient requiring supervision for his cure, where such is possible, or for his permanent care where chronicity has set in, has only very slowly made headway. From the medical point of view it has in the past unfortunately been only too often the case that the physician practising amongst the insane has, from the nature of his circumstances, directed his attention too exclusively to morbid mental phenomena and has tended to ignore those which are concurrent and somatic. Hence the treatment, regardless of pulse-rate, of general nutrition and of the body weight, by almost ceaseless exercise or the treatment of acute excitement by confinement in a "cell" of very limited size loaded with a mephitic atmosphere. On the other hand, until recent years, a study of psychiatry was not included in the medical curriculum, with the result that the doctor in general practice shunned the treatment of states unknown to him, regarded early symptoms as vagaries of character or at any rate as beyond his control, and waited until the patient's conduct became so strikingly morbid that nothing was left to be done save certification and removal to an institution. Fortunately this state of affairs has passed away, and it is recognised that treatment of the mental and physical morbid states should proceed concurrently and be preceded by as thorough examination as is possible of mind and body. With this rule is associated another, namely, that treatment should be commenced at the earliest possible moment. The institution for the insane is, like the workhouse infirmary, only too often a repository for human wreckage, where are recorded the last chapters of histories of illness. The earlier have been sometimes read by the general practitioner, but only too frequently have escaped notice by competent eyes. Prophylaxis and early treatment are as important in psychiatry as in any

other branch of medicine, and the asylum and infirmary would be less full if this were generally recognised. It is to be hoped that in time to come, when cases will be brought forward for early treatment, many a morbid process will be cut short before chronicity sets in. A factor militating against early treatment is the widespread antipathy to an acknowledgment of the existence of mental disorder either by the patient himself or by his family. The causes of this antipathy need not here be discussed, but it is of no use to ignore its most obvious existence, especially while it is unfortunately nourished by legal enactments which make the treatment of this particular class of patients almost impossible, at least for persons of moderate means, without the process of certification and outside an institution. It is natural, then, that initial antipathy fostered by unwise legislation should lead too often to the suppression of evidence of illness until symptoms become so marked that steps have necessarily to be taken, that is, until a time when treatment can effect far less for good than if it had been commenced earlier. It is to be hoped that the general physician, recognising the importance of preventive and early treatment, will impress upon patients and their friends how very much may be done to prevent the development of symptoms, and that he will exercise his influence in the direction of enabling the treatment of such cases to be carried on in general hospitals. Much has been done to draw general medicine and psychiatry into closer relationship. Much, however, remains to be done; but we see no reason to doubt that in the future the numbers of the chronically insane will diminish *pari passu* with attention to the earliest symptoms and to prophylaxis.

No special section has been devoted to classification. No two authorities agree upon this matter, save upon its difficulty, and such division of the subject as is convenient will be found in the headings of sections. Some day, perhaps, ætiology or pathology will furnish us with a wholly satisfactory classification. At present ætiological factors are often unknown, or when surmised overlap each other so confusedly as to be valueless for purposes of classification. Morbid anatomy has furnished us with an immense amount of information, especially as to changes occurring in cases of long standing. Changes occurring in acute cases are less often seen, and from those changes it would be hard, as a rule, to characterise the symptoms as they had been during life. In some cases there would appear to be no discoverable alterations, and it should always be borne in mind that change of function may precede change of structure. So far, then, morbid anatomy supplies grounds not generally regarded as sufficient for satisfactory classification. Assistance in classification might be expected from psychology. The departments of the human mind abstracted by psychology from the continuum of consciousness are for many purposes convenient. Nevertheless, to divide mental disorders into groups corresponding with such departments is impossible. Disorders of affectivity, of memory, of judgment, or of will refuse to be limited in scope by such artificial boundaries. A delusion, a morbid error of judgment, is unlikely to exist without producing elevation, depression, perversion or instability of the affections: that is, of the feelings of attraction towards or repulsion from things upon which thought is concentrated. Similarly depression or elevation of affective tone colour judgment, and our prospects, for instance, are deemed brighter or darker according to the mood of the moment. Defect of memory may alter the affective tone by

eliminating pleasing or displeasing recollections, or by introducing pseudo-reminiscences, and through it there may be such a quantitative diminution of data that judgment becomes difficult, perverted or impossible. Hallucinations lead judgment astray and affect the emotions and the will.

To classify by symptomatology is also futile. Two similar groups of symptoms occurring in two patients may be of different aetiology, run different courses and be, for various reasons, obviously episodes of two different disorders, while two widely differing groups of symptoms occurring in two patients are as obviously episodes of a disorder from which both patients are suffering.

At the present time two sets of opinion contend in the field of morbid psychology, the one holding that many of the causes of insanity, primarily at least, are to be found in interference with normal function, and the other that the causes are for the most part associated with structural alteration, the result of disease or of defective development.

From the psychological point of view the mind is regarded as consisting of groups of thoughts having more or less attraction for or repulsion from each other. Such groups have come, in the language of the school, to be called complexes. These groups are regarded as at times being in harmony and at times in conflict with each other, and it is in the existence of the latter state that disturbance of mental function may arise. In some instances the storm is abated by the invention, more or less conscious, of excuses of varying degrees of plausibility for a line of conduct set in action by a group, that is, by a process of self-deception. So thorough may such a process be that, to every one except the patient himself, the result is seen to consist in the development of delusions. In other cases, the obnoxious group is put out of the mental field; it is avoided or repressed. Avoidance may be sought in the cultivation of other fields of activity: the patient may endeavour to do what, in familiar language, takes him out of himself, and if this process be carried to a morbid length he may pursue the ceaseless, restless and irrelevant activities which characterise some forms of insanity. Avoidance may also be disclosed in the development of opposite characteristics, such, for instance, as an absurdly meticulous accuracy of expression in one who has a repressed complex associated with an untruth or an exaggerated prudery in one who has a complex associated with a love affair.

Evidence of the existence of an inharmonious complex may also be sought in phenomena known as "phantasy" and "projection." In a condition of phantasy the mental state known popularly as "day dreaming" becomes very much exaggerated: the patient takes himself in imagination so much out of his surroundings that he loses in great measure his hold on the objective world, and lives, careless of it, in a fantastic world of his own creation. In "symbolism" various poses may be adopted as expressing fulfilment of a desire which has had no chance of expression in a normal way—for instance, the affectation of the manners and customs of the great or of the beautiful by the mentally small and the physically ugly. Mannerisms and affectation are frequent in dementia præcox, associated with what appears to be considerable mental deterioration, and are indicative of hidden mental processes of which they are the sole manifestation. In "projection" self-reproach for some error of conduct may be changed to the reprobation of others, and the burden on the patient thus removed or lessened.

It will be seen that in these mental processes there is a dissociation of groups of thought which, to secure harmonious mental working, should have been in association and co-operation. Not only, however, must these groups be regarded as dissociated, but as subsequently in a measure isolated, so that the effects produced may be regarded as an absence of certain factors necessary for proper mental activity. Or if, in fact, the groups do influence mental activity the influence is indirect, exerted at the wrong point and at the wrong time and issues eventually in perversion of conduct.

The claims of what may be called the Structural School are nevertheless insistent. Classification is made to depend on anatomical defects and alterations, some of which are gauged by micrometric measurements and the order of the development of the laminæ. There is a class in which neuronie development is imperfect, and which includes various grades of idiocy and feeble-mindedness, epileptic, moral and delusional insanities and hysteria. A second class includes cases known as senile, climacteric, adult or adolescent dementia in which there occurs neuronie degeneration, the change in structure being due to insufficient durability. A third class consists of cases in which the neurons have become subject to the influence of toxic agents, the result depending in part on the power of resistance of the nervous structures, which varies with different individuals. A fourth class is associated with gross cerebral lesions and with the deprivation of some special sense.

Such, in briefest outline, are the positions maintained by the two schools. Except as advanced by extremists they are not mutually exclusive, and the work of the future will probably render them co-ordinated and consolidated.

CONFUSIONAL INSANITY ; INSANITIES OF TOXIC AND INFECTIVE ORIGIN ; EXHAUSTION PSYCHOSES

Definition.—Mental confusion is a condition in which those notions persons ordinarily have of their relations with time and space and of their own personalities become less clear, perhaps to such a degree that the patients, though conscious, no longer recognise their surroundings or realise their own identity. Associated with this inhibition of the action of high psychic centres, there may be a removal of restraint upon lower and more automatic ones, so that agitation, excitement and hallucinations take the place of orderly conduct, equable affective tone, and true perceptions.

Ætiology.—Intoxication from one source or another is the cause of mental confusion. Such intoxication may be acute, as in the case of the infective diseases, for instance, influenza, septicæmia, pneumonia, or enteric; or chronic, as in some forms of gastric, intestinal, cardiac, renal or other organic diseases of prolonged duration. It is possibly premature to assert that exhaustion, whether due to physical strain, such as trauma occurring in war, railway or other accidents, surgical operations, excessive venery, pregnancy, parturition and lactation, privation and starvation, or to emotional stresses, such as continual worry, shock and mental overwork, is a source of intoxication; but evidence at least seems to suggest the existence of "fatigue bodies" as the result of such conditions, and as exercising an influence in the production of symptoms of exhaustion. Until the matter is elucidated, it may be

provisionally held that exhaustion is synonymous with intoxication. If it be not so, then we must add exhaustion to intoxication as a cause of mental confusion. There is no doubt the milder forms of confusion are indistinguishable from the more severe forms of nerve exhaustion, and the latter, running an unfavourable course, may become the former. The two states may, indeed, be regarded as essentially identical, and only as artificially separated by the fact that the one has, in the past, for the most part been treated in asylums, and the other elsewhere.

Heredity looms less large in confusional insanity than in some other forms. There is a strong probability that those of psychopathic or neuropathic inheritance are more apt to fall victims when attacked by some occasional cause, than those of good family history; but in confusional insanity the occasional exciting cause is the prominent factor, and often succeeds in breaking down the resistance of those of unimpeachable inheritance.

Symptoms.—Exaggerated weariness is the most prominent initial symptom. Mental and bodily activities excite no pleasure, and the patient finds it hard work to bring himself to the performance of the ordinary duties of life. The distraction of travel or of pleasure, unfortunately too often advised in these cases, instead of serving the purpose only leads to further lassitude and inertia. Headache, insomnia, irritability, depression and loss of flesh are prominent and constant symptoms. In the case of the acute infective processes the gradual onset, usual in cases of other causation, is compressed into a much smaller amount of time. The feeling of weariness as the result of a few days' illness is then extreme, and of such a degree that the patient may find it almost impossible to raise his hand an inch from the bed. But whether the cause operates with violence over a short space of time, or subtly does its work over an extended period, the march of the symptoms is much the same. The patient has difficulty in concentrating his attention, and as a consequence his memory for immediately past events becomes poor. He displays some degree of confusion and hesitancy as to where he is, what is going on around him, and as to his own identity. He loses his appreciation of time. His power of judgment becomes less, and delusions develop. These are, however, very fleeting, are soon forgotten and replaced by others, and have nothing of the definite systematisation and fixedness of such as occur in delusional insanity. In many cases the character of the emotions also changes, and the patient is not at all or but little affected by what normally would give him pleasure or pain, or, on the other hand, is extremely depressed and miserable, or unduly elated. In extreme cases there may be a suspension of all psychic functions, so that the patient is in a state of stupor. More often a superficially very opposite state of affairs obtains. The highest mental functions being inhibited, there is an exuberance of the lower and more automatic, so that talking or incoherent chattering, restlessness and impulsiveness, issuing in attempts at assault or suicide, take the place of a peaceful stupor. Hallucinations are frequent. The character of the reactions will depend at any given moment upon the nature of the imaginary circumstances amidst which the patient finds himself. He may sometimes appear happy, contented and pleased with his lot, while at other times, and more commonly, he is agitated, anxious, suspicious, frightened and perhaps angry and violent.

Symptoms of bodily illness accompany the mental symptoms. If the

insanity occur with or shortly after some infective process, the special somatic alterations of that process will be observed; otherwise the symptoms may be as follows. General nutrition is not satisfactory, and the patient loses weight even before the onset of the mental symptoms. The blood shows the changes of anæmia of the chlorotic type. The appetite is generally very poor and the ingestion of food resented. The tongue is furred, and the breath offensive. The bowels are constipated, and the stools are often particularly foul. Digestion is frequently impaired, and complaint is made of acid eructations, heartburn and flatulence. The pulse is small, easily compressible and occasionally irregular, its rate is apt to vary within wide limits, but is usually more rapid than normal. The extremities are often cold and cyanosed. Alterations in the urine have been noted in some cases. If renal disease exist, albumin will probably be present in larger quantity, and has been detected even where the kidneys have not been suspected. During an attack, the amount of urine has been found to be diminished as well as the contained solids, notably the phosphates and chlorides, while towards the close of the illness its quantity as well as its solid contents again rises. Indican has been found in some cases. Abnormal signs indicating involvement of the nervous system are not very common; but inequality of the pupils and sluggishness in movement have been observed. The tendon reflexes are very variable; but on the whole more often exaggerated than diminished. In the case of trauma symptoms commence at various times after the accident. If the trauma or shock be sufficiently severe, they may be induced at once, or appear after an incubation period of about a fortnight, or if the trauma has set in motion certain continuing causes, such as suppuration or the expectation of litigation, only after months. When symptoms come on gradually, there is at first some alteration of character with depression, irritability, loss of self-control, blunting of the intelligence and failure in will power. Later the symptoms of confusion as described above develop.

Course.—When due to severe and rapid intoxication, as, for instance, an acute infective disease, symptoms speedily develop, are likely to be severe and to clear up comparatively soon in the course of a few days or weeks: when, on the other hand, as a result of chronic intoxication lasting over many months or years, the symptoms come on insidiously, they last perhaps for many months or years, and pass off very slowly.

Diagnosis.—Certain aspects of confusional insanity have suggested its identity with mania; but the two are in fact by no means similar. In mania, perception of environment is far more rapid than normal, and but little of what is happening escapes the patient. The procession of ideas through his mind is so rapid it is difficult for the observer to keep pace with it, or to follow how any one idea is connected with what preceded or follows it. The memory of the maniac is vastly improved, and he reproduces that which, in his usual state, he has utterly forgotten. His orientation in time and space is perfect. Indeed, far from the mental processes appearing blunted, they are quickened, and are chiefly remarkable in being too rapid to be useful. It may also be noted that the events of his illness are remembered by the patient who has been maniacal; but they pass from the memory of one who has been confused, as does a dream.

Prognosis.—In cases due to trauma, whether psychic or somatic, or to the

shock induced by explosions, the course of symptoms is so varying as rarely to make any definite prognosis at all justifiable. Some such cases get better with astonishing speed, while in others their chronic character is equally a matter of wonderment. Indeed so perverse is the course of nervous and mental symptoms due to emotional shock, or to physical trauma, that both as to its character and duration it is difficult to apply any rules. The somatic symptoms generally improve before the mental. The appetite becomes better, the bowels less constipated, sleep improves, and weight is increased. If unfortunately these improvements be not accompanied, or shortly followed by mental betterment, chronicity may be expected. In the majority of cases patients get quite well. In a few, where the intoxication has been extreme, death occurs from exhaustion.

ACUTE CONFUSIONAL INSANITY

Synonym.—Acute Delirious Mania.

Ætiology.—It may be the accompaniment of some well-recognised infection, as influenza, or enteric, or occur apparently independently.

Pathology.—As might be expected, the changes found in acute delirious mania are more marked than those found in the less severe forms of confusional insanity. The alterations are indicative of meningo-encephalitis. The meninges and brain are hyperæmic, the cortex is oedematous, and the veins and lymphatics engorged. Small extravasations of blood, both in meninges and cortex, are visible to the naked eye, while under the microscope extravasations of small round cells are seen about the vessels. The cortical cells are deformed and swollen, their nuclei eccentric, and perhaps extruded, and the protoplasm shows chromatolysis. Their processes may be broken, and exhibit a varicose appearance. In cases of less severity the naked eye appearances are, as a rule, absent, though degenerative changes may be seen in the cells microscopically. In some cases no change has been discovered.

Symptoms.—The symptoms of severe forms of acute confusional insanity are those already described, but of so serious a character that the syndrome has in times past received a special name. They sometimes, though uncommonly, actually precede the bodily symptoms of the infection, but more often appear when the fever is highest, and the other bodily symptoms at their worst, or when fever has subsided, and the symptoms have disappeared. Sleeplessness becomes complete, the temperature high, and the respiration and pulse-rate much increased. With these bodily symptoms there are associated extreme restlessness, intense apprehensiveness, complete disorientation, hallucinations, usually of a most terrifying character, and very impulsive reactions of conduct. The symptoms and signs of a profound general intoxication develop, the tongue becomes dry and cracked, sordes collect, tremor and subsultus tendinum make their appearance, and the patient dies comatose. When mental symptoms appear on the abatement of the fever, and the other physical symptoms, they indicate the exhaustion from which the patient is suffering. He may be depressed, vacant and vague as to his surroundings, or psychic operations may appear entirely suspended, and the patient may become stuporose, or his appearance may suggest the idea of one having an unpleasant dream.

Treatment.—It is at present impossible to deal radically with the poisons considered to be the cause of this disorder, and efforts can only be directed towards eliminating them and mitigating their effects. The patient should, as far as possible, have perfect rest—both mental and physical. He should be kept in bed, preferably in the open air, and failing this in a thoroughly well-ventilated room. Not only should his activities be reduced to a minimum, but his perceptive apparatus should be stimulated as little as possible by the removal, as far as may be, of sights, sounds and other sources of sensation. He should see only his physician and nurses, and conversation with them should be limited to essential topics.

It is sometimes very difficult to persuade patients to stay in bed, but a good nurse will often succeed in most unpromising cases. If it be found impossible, the patient should be carefully watched and guarded from doing himself any harm. If a sufficiency of attendants cannot be provided, the patient has, perforce, to be placed in a strait-waistcoat, or in a strong or padded room. Resort should only be made to mechanical restraint when human force is not available, or is not skilled and efficient. Very few, indeed, are the properly treated cases in which mechanical restraint can be deemed necessary. In rare instances restraint is asked for by patients themselves, to prevent them from the commission of involuntary impulsive acts harmful to others, or to themselves.

In the acutely delirious cases it may be desirable to give the patient a general anæsthetic for the purpose of feeding and administering drugs through a tube. The opportunity may also be taken to wash him and change his clothes.

The condition of the bowels should receive careful consideration. Patients are often known to be constipated; but there are many with a reputation for regularity, who are only found to be constipated when the character and quantity of the fæces has been examined. That the bowels should be regularly and effectively evacuated is of the utmost importance, and this must be secured by drugs or enemata. Food should be given in ample quantity, and should be as nutritious and as easily assimilable as possible. Patients have great difficulty with the ingestion of food, and here, again, it is necessary not to be content with an assurance that food is being taken, but to inquire precisely as to its nature, frequency and quantity.

Where there is agitation, restlessness and insomnia the question of the administration of sedatives and hypnotics arises. Such drugs should always be tried, though it is not possible beforehand to be confident that success will follow their use. The sedatives and hypnotics may be used in turn, in varying doses, administered at different times, and it will be seldom found but that some drug, given in a particular dose, at some particular time, does yield a good result. Too often their usefulness is denied, because they have been given in doses too large or too small, and at the wrong time. Treatment should be carried on along the same lines for months, or at any rate until the patient's physical condition has considerably improved, and he has returned to his normal weight, or surpassed it. It should then be very cautiously relaxed, and the patient allowed very gradually to do more, but not to overtax his strength. When the patient has at length lost all symptoms, and is in good physical health, he should go for a change before returning to work.

ALCOHOLISM

Alcohol is taken in excessive quantities for a variety of reasons, among the commonest being social convention, its effect in producing a general sense of well-being and, in most of its forms, its pleasant flavour. A family history of alcoholism, of epilepsy and of mental and nervous disease is quite frequent in those addicted to excess, but it must be remembered that home influences and education, where the parents suffer in any of these ways, are unlikely to be very satisfactory, or to result in the production of persons properly informed or with a sufficiency of self-control. The bad example of parents is very easily followed by children, and a boy or girl may be brought up in what may be called an atmosphere of alcoholism without realising that very excessive amounts are being consumed by those around or that such excess tends to physical and mental decay. If allowance be made for these circumstances there are yet families whose members are peculiarly susceptible to the temptations of alcohol: in successive generations certain members take to drink, or in the same generation brother after brother succumbs. Family histories are not easy to obtain. In the wealthier and more educated classes unfortunate histories are suppressed: in the less wealthy and educated the history of forbears soon passes into oblivion.

Certain persons, as a consequence of their mental attitude, whether their dispositions be mainly inherited or cultivated, seem unable to grasp the bearing of the course upon which they have entered. Advice, admonition and even demonstration of the bad effects of alcohol upon them are entirely wasted; they lack any sense of appreciation or, which from a therapeutic point of view is as hopeless, they deliberately thrust consideration of the subject out of mind. Such persons belong to a class the members of which disclose lack of judgment in very numerous ways. It is not that they drink from imperious need, as do some alcoholics, but their range of mental outlook is singularly limited.

The circumstances of an individual are of great importance. Many seek in wine relief from mental worry, from weariness of mind and body and from pain. That alcohol has effects in the relief of these states is a matter of such wide general experience that they can only be denied by the fanatic, but the danger zone is reached when it becomes regarded as a panacea and when, therefore, it is taken in excess. The question of what is meant by excess is at once raised. An amount of exercise, food or sleep which is not only adequate but necessary for one individual may be wholly inadequate or excessive for another, and the same is true of alcohol. Some persons, particularly females, cannot stand the smallest quantity, while others take large amounts for many years without being the worse when judged by any available method. The state of the particular individual under inspection can alone present the data from which the physician must endeavour to elucidate the problem as to the amount of alcohol, if any, which is safe.

Alcoholism is sometimes a symptom of such grave mental disorders as general paralysis of the insane, mania, epilepsy and senile degeneration. Perhaps never before in his life given to excess, the patient suffering from commencing general paralysis, mania or senility, to the surprise of those who have known him well, takes to the immoderate use of alcohol: or a

patient, suffering from some variety of epilepsy, and as a rule of quite sober habits, from time to time has bouts of furious drinking.

Symptoms.—A single overdose of alcohol may produce acute symptoms, the amount constituting an overdose and the severity and character of the symptoms varying very largely. Repeated doses may in time produce symptoms called chronic, because they are of prolonged duration. Here again the frequency and amount of the doses and the character of the reaction of the tissues vary very much. Acute and chronic symptoms often occur together, the former being superimposed upon the latter and being as a rule due to the ingestion of a large amount, in addition to the habitual overdose, but they are sometimes the result of the sudden stoppage of the accustomed amount.

Most persons have, when sober, some degree of self-restraint, and the diminution of this restraint is one of the earliest symptoms of the influence of alcohol. Quite a considerable number of persons become talkative, witty and even instructive who ordinarily, because shy, prudent or otherwise restrained, are silent, dull and uncommunicative. Diminution of restraint is not, however, always thus advantageous, but passes on, as the amount of alcohol taken increases, to looseness of conversation and conduct. Regard for conventional decency is lost, and the patient may commit silly, disagreeable, outrageous, or even criminal acts. Psychic weakness thus indicated may extend later to more automatic functions, so that speech becomes thick and unintelligible, and the gait and other movements awkward or impossible, and eventually sleep or coma supervenes. In rare instances, paralysis extends to the vital bulbar centres and the patient dies. In certain cases symptoms take special forms. Excitement may be intense with much noisiness and violence, convulsions may occur, or the patient may develop delusions of persecution or of grandeur, or he may become depressed and even suicidal. As a rule the symptoms rapidly clear up, at any rate if their cause be withdrawn.

ACUTE ALCOHOLIC DELIRIUM

Synonym.—Delirium Tremens.

The symptoms of acute alcoholic delirium are usually superadded to those of chronic alcoholism. They may occur when alcohol is suddenly withdrawn from a patient who has become habituated to large quantities. Emotional stress, trauma or illness is sometimes the occasion of their appearance.

The first symptom to attract notice is sleeplessness. The patient looks haggard and worn and his hands and tongue are very tremulous. His tongue is furred and his bowels constipated. The pulse-rate is increased. He is apprehensive in mind and restless in body. In the course of a day or two, during which he becomes more depressed and excessively irritable, visual, auditory and other hallucinations develop. These are of a most unpleasant character. The patient sees vermin, reptiles, wild beasts or human enemies, armed with all sorts of weapons, approaching to attack him, and he may also hear them hissing, roaring or uttering threats. There is a considerable degree of confusion in the patient's mind, and he loses knowledge of his surroundings, of himself and of time. Mixed in mind and terrified in feeling,

the patient's conduct is impulsive and violent. He shrieks with horror at the sights before him, or at the contact of the reptiles or other noisome beasts, and may seek to avoid them by flight or by jumping out of the window, or, on the other hand, he may attack them with anything handy which can be used as a weapon of offence. The aspect of the patient is that of extreme anxiety or terror. The face is congested and the eyes bright and bloodshot. The temperature may be a little raised. The pulse-rate is rapid.

Course.—In some cases the patient, worn out by want of sleep, restlessness and agitation, lapses into a state of profound asthenia, becomes comatose and dies, while in others the confusion, the delusions and the hallucinations become less pronounced and continue indefinitely as chronic confusional insanity. In a majority of cases in a few days the physical condition improves, the tongue cleans, sleep returns, the pulse-rate diminishes, appetite improves and the tremor becomes less marked, while the mental state gradually improves. Hallucinations become less terrifying and slowly disappear, and the patient again begins to realise his surroundings.

Treatment.—The first requisite of treatment is adequate care of the patient. If the conduct be impulsive and violent the patient must necessarily be restrained, and this is best effected by a sufficiency of tactful, kind and powerful attendants. If attendants of a proper sort and in sufficient number cannot be provided, it may be necessary to use a strait-waistcoat or other mechanical appliance. Recourse should only be had to physical restraint when absolutely necessary. Every effort should be first made by kindly persuasion to comfort and reassure him. Bed is the best place for the patient, and he is there better under control than if up and wandering about. He is almost certain to have had too little food, and he should be persistently fed with milk and other easily digested foods. If the patient has been drinking up to the time of the commencement of the symptoms, the amount of alcohol he has been taking should, so far as possible, be ascertained. This amount may be reduced by one-fifth each day until on the sixth day no alcohol is taken. The reduction of a fifth a day must only be taken as a rough guide, and may be greater or less according to the strength of the patient, his tolerance for alcohol, and his reaction to treatment. If the patient has not been drinking within two or three days from the commencement of symptoms, or has been vomiting his drink almost as soon as it has been swallowed, symptoms may be mitigated by the administration on the first day of treatment of half the amount of alcohol to which he has been accustomed. Thereafter a reduction of a few ounces is made each day until none is given. Such a gradual withdrawal or tapering is not always practised, and some prefer to stop alcohol abruptly as soon as the patient comes under treatment. If digestion is defective and there is vomiting, the stomach may with advantage be washed out with hot water and bicarbonate of soda, two drachms of the latter to the pint of water. When the health is fairly good, a large dose of calomel may be given, and in any case the bowels should be kept well open. Sedatives and hypnotics should be given, potassium bromide being particularly valuable before the acute symptoms have arisen and when they are subsiding. They are not always a success, but should at any rate be tried until found to be useless.

DIPSOMANIA

Definition.—The term dipsomania is employed with much looseness, but it is as well conventionally to restrict it to a thoroughly defined syndrome. It signifies an imperious tendency towards an act or a line of conduct which is scarcely, if at all, influenced by judgment, and consists in the ingestion of alcohol.

Symptoms.—Between times the patient may be entirely abstemious or perfectly well able to keep himself within bounds, but on the occurrence of the impulsion he becomes in this respect an automaton and obeys the tendency to act without power of resistance. The impulsion to drink is often preceded by a few days of alteration of disposition, evidenced by irritability and depression, during which it gradually develops and gathers strength, and at last overwhelming the judgment a drinking bout is commenced.

Treatment.—If prodromal symptoms are known to occur, advantage should be taken of them as a warning, and endeavours should be made to control the movements of the patient. Sedatives may also be administered. Suggestion is often of great help in cases of this description and should be employed during the healthy intervals as well as in the prodromal stage.

MANIA A POTU

Another form of excitement induced by alcohol is known as Mania a potu. Persons in whom it occurs are usually of a neurotic diathesis and their family histories often disclose instances of insanity, epilepsy and nervous disease. The attack is often induced by a very small amount of alcohol, acting on one of quite abstemious habits. Immediately alcohol is taken, in amount perhaps only a glass of wine, the patient becomes acutely excited, noisy or violent or both. The attack lasts from some hours to a few weeks, when the symptoms abate and the patient becomes again quite normal.

Treatment.—Treatment is obviously of a preventive character, and alcohol should be absolutely forbidden. When symptoms of excitement occur they must be treated as if of any other causation. Having in consideration the short time during which attacks usually last, certification should be avoided in all cases where proper provision can be made for nursing the patient outside a licensed institution.

CHRONIC ALCOHOLISM : DEMENTIA

Having now reviewed the groups of acute symptoms associated with the occasional excessive consumption of alcohol, there remain to be considered the mental effects of its frequent consumption in excessive quantity over long periods of time. Some of the mental effects of chronic alcoholism are so striking that they have led to grouping of cases in which they occur in several categories, but underlying that and common to all forms is the gradual decline of mental level known as alcoholic dementia.

Pathology.—In cases of long-standing alcoholism the meninges are found

to be thickened and adherent to a cortex more or less atrophied. The arteries are degenerated, and there may be appearances of recent or old hæmorrhages of varying size. In acute cases there may be general congestion and serous or bloody effusions. In many cases the anatomical appearances are normal.

Symptoms.—The appearance of the symptoms is very gradual. Dementia may reveal itself in the course of a few, or many, years after excess has become established, and in some persons after the consumption of a daily dose apparently quite inadequate to produce any bad effect in the majority. Subtle alterations in character are first to attract attention. The patient becomes less nice in personal habits, less discriminating in the choice of associates and less punctual in the performance of social or business duties. His attention is found to be hard to hold and he tends to ramble in conversation. Judgment becomes of poorer quality, less well founded and either unduly hesitating or hasty. Volition displays weakness, in obstinacy or in irresolution. Gradually such defects become more pronounced and the patient is found to be untrustworthy either socially or in business. Appointments are neglected for no pretext or for such as are manifestly absurd. Silly quarrels are fastened upon good friends, and even more absurd partialities are shown for those that are bad. Conduct becomes objectionable, obscene or even criminal. Loss of memory is very marked. At first it is due to the inability of the patient to fix his ideas by an adequate effort of attention; later, to a loss of the power of reproducing past memories; and lastly, to a loss of the power of conservation. The mental state may be reduced to a very low level, where nervous reactions are purely automatic and only a flicker of intelligence can be roused by the notion of the desired drink. With mental deterioration are associated those numerous somatic symptoms indicative of degeneration of various tissues.

Hallucinations of the special senses, but particularly of hearing and of sight, may occur at any stage of mental deterioration. So notable and long lasting may be the hallucinations that the condition has received the name of *chronic alcoholic hallucinosis*. The patient may see animals, often reptiles, but they have not the terrifying effect of those seen in delirium tremens. He may also hear voices which often call him names, or threaten him. Delusions are also not uncommon and are more or less fixed and systematised, but never to the extent met with in delusional insanity. They are of many varieties, but those of jealousy, suspicion, persecution and grandeur are the commonest. To this condition the term *alcoholic paranoia* has been applied.

Cases at times very closely resemble general paralysis of the insane. The delusions may be exactly those of the extravagant magnificence met with in that disease and there may in addition be several of its abnormal physical signs. The movements for the production of speech may be weak, tremulous, unduly prolonged and badly co-ordinated so that the indistinct, hesitating and slurring utterance of the general paralytic is produced. The pupils may be sluggish in reaction and unequal in size and the tendon reflexes may be lost or increased or unequal. There is, as a rule, much tremor. Such cases are included under the term *alcoholic pseudo-paralysis*.

Diagnosis.—In the cases of pseudo-general paralysis just described it may only be possible to make a diagnosis by examining the cerebro-spinal

fluid. In general paralysis this will give a positive Wassermann's reaction and a leucocytosis. In alcoholism, unless complicated by syphilis, which unfortunately it often is, Wassermann's reaction will be negative and there will be no leucocytosis.

KORSAKOFF'S POLYNEURITIC PSYCHOSIS

Ætiology.—In this disorder mental symptoms are associated with multiple neuritis. The condition is not only the result of alcohol but is also met with as the consequence of other intoxications, of infections and of exhaustion. The special symptoms come on rapidly during the course of chronic alcoholism.

Symptoms.—At first these consist of anxiety, agitation, restlessness and hallucinations. These become less marked in about a week, but there is considerable confusion and forgetfulness. The patient fabricates stories, pseudo-reminiscences, which he relates and in which he thoroughly believes. The symptoms and signs of multiple neuritis, such as pain and tenderness along the course of the nerves, loss of muscular power, abolition of tendon reflexes, paræsthesiæ and anæsthesiæ, also develop. There is, as a rule, considerable emaciation. The action of the heart is feeble and irregular.

Course.—Such symptoms may last for several months and then pass away gradually, though complete recovery is rare when alcohol is the cause.

Prognosis.—If the patient be young, of good disposition and of normal bodily health and can be persuaded to stop the use of alcohol, the prognosis as to symptoms of both mind and body is good. Often, however, the patient is of such enfeebled judgment and will that his disposition is not favourable to his co-operation in his cure.

Treatment.—The fundamental treatment of alcoholism lies in endeavouring to stop the patient from taking the poison. Where this is not possible, attempts should be made to persuade him to enter an institution. The treatment carried on within special institutions varies very much, and various modes are vaunted by various practitioners. A great point has been gained when a patient has consented to enter an institution, and if he leave it without having taken alcohol for some time, in better general health and with strengthened judgment and will, the object of treatment has been achieved. There are, doubtless, those who would do well to remain in institutions altogether, for they are persons whom nothing will restrain from drinking save the physical impossibility of getting alcohol. To deal with such persons outside an institution is, from the physician's point of view, idle; advice and all forms of psycho-therapy may be administered, but without the goodwill of the patient himself are useless. In some cases treatment by suggestion, whether in an institution or not, is of great value. In all cases efforts should be made in every way to raise the general standard of health as far as possible.

DRUG HABITS

MORPHINOMANIA

The habitual consumption of opium either by the mouth or by smoking results in symptoms almost precisely the same as those caused by the habitual

hypodermic injection of morphine. In the East the opium eater or smoker asserts the drug is sedative or restorative, and he consumes it for this reason rather than for the pleasure of the preliminary excitement. In countries inhabited by a white population the usual method of administration is hypodermic and the preparation is morphine.

Ætiology.—The power of morphine to afford immediate relief from pain and discomfort, mental or physical, constitutes at once its value in the hands of the physician and its danger in the hands of the patient. The neurotic, degenerate and ill-balanced are particularly prone to bad habits of all descriptions and to the drug habit in particular. Curiosity sometimes tempts persons to try the vaunted delights of opium and morphine, but perhaps more usually some trifling and temporary disorder suggests the use of the drug, and the patient, unable from weakness of judgment or will to abandon it when its use is over, continues to take it as a matter of habit. To some few persons the drug has been given in the first instance by a medical practitioner for the relief of the symptoms of such chronic maladies as rheumatism, asthma, dysentery, dysmenorrhœa, migraine or tabes dorsalis. In the case of chronic disorders of a painful character, the physician should ever remember the possible consequences of the prescription of opium and its derivatives, and should only in the last instance have recourse to them. The professions and occupations which have special means of access to drugs, and some knowledge of their actions, such as those of medicine, pharmacy and nursing, provide a particularly large number of morphinomaniacs.

Symptoms.—At first, and for a period of time which may be months or years, the effects of the drug are only such as are pleasant to the patient, and consist in feelings of exuberant mental and physical well-being and power. In some persons there is also generated a dreamy state into which many varieties of delightful hallucinations enter. Such states are succeeded by feelings of lassitude and depression, the more intense as time passes. Before long the pleasing effects become shorter and the subsequent depression deeper and of longer duration, and to relieve this another and stronger dose has to be taken. With the establishment of the habit, and the concomitant chronic intoxication, mental and physical symptoms develop. The patient gradually loses all sense of moral values, but at the same time, while under the influence of the drug, may be amusing, clever and capable of working well. He is ingenious in excusing his own faults, and in saddling others with blame. The occasional failings of the neurotic temperament are converted into permanent symptoms, and the patient becomes untruthful, untidy, unpunctual, dirty and dishonest. The faculties of attention, memory, judgment and will deteriorate. Insomnia becomes marked. Physically, the patient becomes thin, sallow and prematurely old in appearance. The heart's action becomes feeble and sometimes intermittent. Perspiration is usually scanty, but is sometimes excessive. The body temperature falls below the normal. The mouth is dry and the gums shrink. Dyspepsia, vomiting, diarrhœa and constipation are common. Myosis is usual. The reflexes are diminished, and there is sometimes hyperæsthesia and sometimes anæsthesia of the extremities. Albuminuria develops in certain cases. The functions of the sexual organs cease. Abscesses from the use of contaminated needles are not uncommon, and may be the starting-point of septicæmia. The daily quantity used may vary from 3 to 40 grains. With

gradually increasing doses, the amount discharged by the bowel and kidneys diminishes until none is excreted at all. It would appear probable that the tissues acquire a power of destruction of the drug.

As time goes on a chronic state of mild confusional insanity becomes established, with delusions and hallucinations, while the general mental level becomes slowly lowered. The concurrent physical deterioration eventuates in a state of cachexia, and death usually results from heart failure, septicæmia or tuberculosis.

Diagnosis.—When the patient or his friends furnish a correct history a diagnosis is easy. When, however, no history is given or is deliberately falsified, as is often the case, a diagnosis is of extreme difficulty. An account of changes in character, temper and general condition occurring at short intervals of time, with periods of well-being associated with contraction of the pupils, is suggestive, and the diagnosis may be regarded as certain if the marks of the needle are also present. A definite diagnosis may also be established by isolating the patient for twenty-four hours, and at the same time preventing access to the drug.

Prognosis.—A morphinomaniac persisting in his habit and in no way controlled by external forces is on the high road to death, his rate of progress depending on the vigour of his constitution, the amount of the drug consumed and his financial circumstances. One initially feeble in physique and badly circumstanced will probably die in a few years, whereas one of good constitution and living in comfortable surroundings may last for many years. In the case of those who voluntarily or forcibly come under treatment, and are permanently weaned from the drug, the prospect of health and life is almost as good as if they had never had the habit. Unhappily, in the majority of cases, even though treatment has succeeded in breaking the habit, and raising the patient's health to a high level, relapse sooner or later occurs, and the custom becomes rapidly re-established.

Treatment.—Unless the patient consents to reside in a special house of treatment, to obey the instructions of the physician and submit to a régime for a period of several months, treatment is practically of no value. It is essential that it should be impossible for the patient to obtain the drug, and in consequence the choice of trustworthy attendants is of the greatest importance. On admission, the patient should take a bath, his clothes should be removed and with his other belongings carefully searched. A watch should be kept on everything sent to him from the outside world, and it is as well to explain at the outset that all letters and parcels will be examined.

The treatment of morphinomania consists essentially in the withdrawal of the drug. Abrupt withdrawal is dangerous and may result in collapse or death, while the attendant suffering is intense. The method of withdrawal most usually adopted is gradually to diminish the amount taken, the rate of diminution depending upon the general condition of the patient and the amount of morphine he has been accustomed to consume. The process of suppression may last a fortnight. On the first day, the dose given is diminished by one-fourteenth of the patient's maximum dose, and on each succeeding day the dose is further diminished by the same amount. In this way at the end of the fortnight no morphine will be given. The patient should be kept in bed while the withdrawal is taking place, and for at least one week after the drug has been suppressed. His mental depression and anxiety

and physical distress may be largely controlled and alleviated by the administration of such sedatives as the bromides, grs. x-xx, 6tis; hyoscine hydrobromide, gr. $\frac{200}{100}$ - $\frac{100}{100}$, once or twice a day hypodermically or by the mouth; amylene hydrate, ℥xxx-3iss, or paraldehyde, 3ss-3ij. The doses of these drugs will in all probability have to be large to produce the desired effect, and a careful watch must be kept upon the action of the heart to prevent its undue depression. Heart failure must be met with the usual remedies. Food of good quality and in large quantity should be given. As dyspeptic symptoms are common, the details of diet may have to be carefully laid down. The bowels should be freely opened with suitable aperients or enemata, to eliminate the accumulated drug. As the symptoms attending abstinence abate, the patient may be very gradually returned to a normal course of life, and every means should be taken to improve the appetite, increase the body weight and diminish anæmia. A course of suggestion under hypnosis, to fortify the patient's resolution to avoid the drug in the future, should be instituted.

THE COCAINE HABIT

This habit is generally consequent upon the medicinal use of the drug, and has been known to begin with its employment in the cure of the morphinomaniac. It may be taken by hypodermic injection or in the form of snuff or lozenges, and the daily dose has been known to reach as much as 40 grains.

Symptoms.—The symptoms are like those of the morphine habit, and a dose is followed by similar feelings of well-being and self-satisfaction. The pleasant effects last a shorter time than those of morphine, and are succeeded by physical prostration and mental depression. Sometimes the symptoms are like those of acute intoxication by alcohol. After a varying time, the patient commences to suffer from weakness, loss of appetite, nausea and other dyspeptic symptoms, tremulousness, paræsthesiæ, hallucinations and delusions. Hallucinations are often connected with the skin, and the patient feels that he is infested with insects or small crawling animals. The delusions are frequently of persecution and conduce to dangerous reactions of conduct. Confusional states, agitation and heart failure result from chronic cocaine intoxication. The habit is even more degrading, both physically and mentally, and more difficult to break than the morphine habit.

Treatment is the same as for Morphinomania.

THE VERONAL HABIT

Veronal taken habitually in large doses and at frequent intervals, uncontrolled by medical supervision, is apt to eventuate in dyspepsia, cardiac weakness, pulmonary congestion, cutaneous rashes, polyuria or suppression of urine, hæmaturia and albuminuria. Its effect on the mind is to produce a state of obfuscation which may amount to confusion, with disorientation, general mental debility, depression, transitory and varying delusions and hallucinations. Treatment consists in gradual withdrawal, during which the heart must be most carefully watched. Other hypnotics may have to be given during withdrawal, and their administration should be kept most strictly in the hands of the medical attendant.

THE CHLORAL HABIT

Symptoms.—The symptoms of this habit have their chief incidence upon the cardio-vascular and gastro-intestinal systems. The powers of the mind gradually deteriorate, but more marked mental symptoms rarely occur.

The Treatment is as for Morphinomania.

THE ETHER HABIT

The desire for this drug does not equal in intensity that for morphine or cocaine. The symptoms and treatment are similar to those of alcoholic intoxication.

MENTAL SYMPTOMS OF PELLAGRA

Symptoms.—Mental symptoms are of a confusional character, and would appear to indicate intoxication or exhaustion. The onset is slow, and insomnia is the first symptom which attracts notice. The patient gradually loses his memory, gets muddled in mind, more and more disorientated, and eventually so befogged as to become stuporose. Hallucinations and delusions may develop and, according to their character, may result in reactions of excitement or depression. The attacks of mental symptoms tend to pass off with treatment by rest, nourishment, and sleep; but the patient often relapses when he returns to his usual surroundings, work and food.

Course.—The course is slow. The mental level tends to become lower with each exacerbation of symptoms, and eventually dementia is established.

Treatment.—It is desirable that the patient should be removed from the locality in which he has become infected. Hexamine, mercury and arsenic may be administered, the last in the form of liquor arsenicalis, atoxyl or salvarsan. General hygienic measures are important. Deficiency in vitamin and protein intake has been suggested as the cause of pellagra, and particular attention should be paid to the adequacy of these substances in the diet.

INTRACRANIAL TUMOURS, GRANULOMATA AND ANEURYSM

The mental symptoms are those of confusion, somnolence and stupor. There may also be hallucinations of the various senses and delusions of rather vague character. Mental symptoms are more likely to occur when the neoplasm is situated in or near the frontal lobes of the cerebrum.

If there is any suspicion that the tumour is a syphilitic granuloma, anti-syphilitic measures should be taken. In other cases, the question of operation may be mooted. Operation may be undertaken only for the relief of pressure and consequent pain and blindness, or it may be radical in the hope of removal. If mental symptoms are present the lesser operation is the preferable.

SYPHILIS AND MENTAL DISORDER

In the secondary stages of syphilis there may be, as in any acute infective state, symptoms, more or less severe, of confusional insanity. Acute delirium, of varying duration, with hallucinations, agitation and restlessness may occur,

or melancholic anxiety and perhaps stupor. In syphilitic cachexia there may also occur, as in states of exhaustion, whether due to acute or chronic illness or to overwork and worry, the symptoms of confusional insanity. General paralysis of the insane is now universally admitted to be of syphilitic origin. Idiocy and juvenile general paralysis are the mental diseases associated with congenital syphilis. Patients with tabes dorsalis sometimes present mental symptoms. Some such are probably cases of general paralysis, while others are cases of confusional insanity and due to exhaustion.

Besides these mental disorders due to the virus of syphilis there are others not due to it, but based upon ideas about syphilis. Some persons have an abnormal fear of catching the disorder, perhaps by some extraordinary mode of chance contagion, while others, having had it, have abnormally acute fears as to its consequences. Such persons are often psychasthenic, ill-balanced or degenerate, and their fears on the subject of syphilis may be combined with or may alternate with abnormal fears on other subjects.

MENTAL SEQUELÆ OF ENCEPHALITIS LETHARGICA

The mental sequelæ of encephalitis lethargica are very varied. Some consist merely in the patient's mental level being a little lower than before the attack. Beyond this comparatively trivial alteration are many gradations of severity right down to such defect as amounts to imbecility. In addition to defect there may be more definite symptoms reminiscent of other mental syndromes. Mental symptoms may occur during the original attack (see p. 148) and be indefinitely continued when it has subsided; or they may appear after a period of days, months or even years of seeming good health. The most common of the symptoms is apathy, associated with disinclination for any activity. The apathy may be accompanied by drowsiness and prolonged periods of sleep. In some cases uncontrollable sleep during the day alternates with complete wakefulness at night. Automatism occasionally develops.

The patient's disposition may become altered, and there may be such a diminution of the affections as strongly to suggest dementia precox. Or the patient may be irritable and anxious and develop various phobias. Among the most striking and pitiable symptoms are extraordinary perversions of character, the patient becoming untrustworthy, uncontrolled and depraved. A few cases pass into a state of euphoria and even exaltation. Maniacal and melancholic symptoms may occur. In other cases symptoms suggest an exhaustion neurosis or psychosis. Attention and memory, for both recent and remote events, become enfeebled. Confusion, hallucinations, delusions and violent conduct may follow.

Where there is feeble-mindedness the defect may be of an all-round character, but may have a special tendency to be irregular in its incidence upon intelligence.

The prognosis as to the mental sequelæ of encephalitis lethargica is grave, but some cases ameliorate and some few get quite well.

MENTAL DISORDERS ASSOCIATED WITH EPILEPSY

Ætiology.—A history of fits, major or minor, is not always to be found in the family or personal histories of epileptic insanity. It is scarcely, how-

ever, to be doubted that the episodic mental disorders ascribed to epilepsy are due to the same exciting cause as are fits, whether major, minor or visceral. On this part of the subject therefore the chapter on Epilepsy should be perused.

Symptoms.—The symptoms of epilepsy, so far as they are mental, may be divided into two groups: one comprising episodic attacks, analogous to somatic fits, which pass under the term "psychic equivalents," and another which may be characteristic of the entire mental life of the epileptic individual. It is to this latter group that reference will first be made.

The symptoms here to be described do not occur in all cases. Many who suffer from epilepsy present no mental symptoms at any time in their lives, are of normal attainments and indeed sometimes of exceptional ability. On the other hand, varying degrees of mental defect are very common. The patient may be but very slightly below the average level, or an idiot incapable of the most rudimentary education, or at some degree between these states. Whatever the intellectual level (provided it be sufficiently high to admit of manifestations of character), egoism, self-importance and idleness are likely to be much in evidence. At a low level of intelligence this may not be of much importance, since the patient is likely to be always under control, but at higher levels, when he is considered to be capable of living an ordinary life in society, such qualities may prove injurious both to himself and to others. In a yet more pronounced variety these features of the epileptic's mental make-up result in alcoholism and crime or form the basis of various sorts of insanity. Such symptoms may persist throughout a patient's life without a declension of mentality; but, on the other hand, it often happens that a patient starting at a low level descends to those yet lower, or starting at a normal or high level gradually descends until almost all sign of intellectual life is extinguished. This process may be observed both when the patient has suffered from somatic symptoms, or from psychic symptoms alone or from the two sorts conjoined. The symptoms are of most gradual approach, and the mental enfeeblement is at first disclosed by a deterioration of the higher functions and diminished restraint over the lower. Patients become yet more selfish and sly and less amenable to healthy suggestions. They become gluttonous, and may be guilty of various sorts of sexual crime. Such mental accomplishments as may have been acquired are lost, and the tendency is towards a state of complete dementia in which nothing is left of the higher faculties, and existence is one in which vital functions continue to be automatically performed but all signs of mental activity are absent.

Episodic mental symptoms may be associated with, or occur independently of, the somatic symptoms. Those occurring in association with fits may precede, be concurrent with, or follow them. The aura of a fit may sometimes be mental. Hallucinations of special senses are not infrequent and may be of definite sights, sounds, smells or tastes, or, most commonly, of quite vague and ill-defined sensations of either the special senses or of the so-called common sensibility of the body in general or of some special part of it. Another mental change sometimes to be noticed is some degree of alteration in the patient's character. Excitement, depression, obfuscation, obstinacy, or a fear of impending calamity may be the recognised heralds of an attack and as such may be of importance. The mental symptoms occur-

ring during an attack can scarcely be marked, seeing that the patient is unconscious in a vast majority of cases. Nevertheless, some patients affirm they have preserved some degree of awareness of their surroundings, accompanied by a feeling of overwhelming horror. It is quite likely patients miscalculate the time of the occurrence of such symptoms, and that they, in fact, experienced them just as consciousness was being lost or regained. However this may be, there is no evidence that such feelings eventuate in any sort of conduct during the convulsive stage of the attack. After an attack is over, a state of mental confusion is very common. In some patients the confusion only amounts to a muddled feeling, while in others the disorientation is so complete, that persons and things are not recognised, and the patient may even appear to be living amidst illusory or hallucinatory sights and sounds. In some cases the reactions resulting from this state of affairs may be very violent or, on the other hand, orderly and quiet, but absurd and wholly unconnected with the normal course of the patient's life.

Alternating with somatic fits there occur in some persons groups of mental symptoms, called psychic equivalents, which are regarded as of similar causation. In other persons similar groups of symptoms occur without any sort of bodily seizure and are regarded as due to epilepsy, because they resemble the group of mental symptoms met with in those who have, or in the past have had, somatic attacks. Symptoms, whether alternating or isolated, come on with great rapidity. The patient rapidly becomes confused and disorientated in time and space, and the void thus left may be filled with hallucinations of all sorts, some vague and some quite clear and well defined. The capacity for healthy judgment is diminished, and under the influence of the hallucinations perversions of judgment, or delusions, develop. Such delusions may be of a depressed, hypochondriacal, grandiose or persecutory character. The conduct of one whose mental capacity is diminished and who is suffering from hallucinations and delusions, necessarily differs from the normal, and in the case of the epileptic is often extremely violent. So suddenly are acts of violence committed and of so extreme a nature that such patients are among the most dangerous of insane persons. Epileptic mental symptoms develop with great rapidity, last but a short time, varying from a few hours to a few days, and quickly pass off. With the attack there may be tremors of the tongue, face and hands, some disorder of speech and an unsteady gait. When an attack has passed off the memory of events which have occurred during it is extremely hazy, or oftener there is none at all. In a few cases of epilepsy a condition of automatism occurs, the patient suddenly commencing a line of conduct different from that habitual to him, following it for a time, and then suddenly resuming his usual life, wholly unaware of what he has been doing. This period of alienation of the patient from his habitual self may last for a few hours only or may be prolonged for months, and during it the patient may perform acts which are absurd, improper or criminal.

Treatment.—The hygienic, dietetic and drug treatment of the mental symptoms of epilepsy is similar to that for the somatic forms of the disorder. When the mental symptoms are those of extreme excitement care at an asylum is almost inevitable, but it must be remembered that such patients often rapidly recover and may be well again by the time they reach the asylum door. Further, bearing in mind the impulsive violence of the symptoms,

ample provision should be made to prevent the patient from attempting to do any harm.

MELANCHOLIA

Definition.—Melancholia is the term applied to an abnormal mental state whose outstanding feature is the misery of the patient, shown by his facial expression, speech, attitude and movements.

Ætiology.—A family history of mental disorder is not uncommon. In the individual, melancholia is often preceded by disappointment, overwork, worry and some variety of bodily ill-health. Its incidence is chiefly upon the retiring, sensitive and conscientious. Affection denied expression, owing to loss of its object or to lack of opportunity, may in some persons turn itself in upon itself and, identifying itself with the external agent of its disappointment, take the blame and inflict punishment. Hence ideas of disease, ruin and damnation. Many of the symptoms suggest chronic intoxication, the poison perhaps being elaborated in the gastro-intestinal tract. It most commonly occurs in the fourth, fifth and sixth decades. Symptoms often appear at the menopause in women and in the fifth and sixth decades in men, and have suggested the term "involution psychosis."

Pathology.—Alteration in the cells of the cortex has been described by some, and the appearances of slight meningo-encephalitis by others. These morbid changes are not, however, constant. In cases lasting many years, wasting and other degenerative changes in the brain are often found.

Symptoms.—There are four marked clinical types of melancholia: (1) simple melancholia; (2) melancholia with delusions; (3) melancholia with agitation; (4) melancholia with stupor.

SIMPLE MELANCHOLIA

Before the illness has shown definite mental symptoms it may have been noticed that the patient's appetite has been very poor, his tongue furred and his breath foul. His weight may have diminished, and he may have complained of dyspepsia and constipation. With these symptoms there may be a feeling of diminished power for work, of attention and will, with vague præcordial and epigastric distress and apprehensiveness. Later, this develops into fearfulness as to the correctness of his own conduct, the state of his health, the condition of his monetary fortune and his social status, or the welfare of relations and friends. He experiences profound and unwarranted sadness about some particular thing or about things in general, and he cannot detach his mind from this line of thought. He often complains he does not see things as he did before, and they seem strange and different. Perhaps his viscera betray their presence by unpleasant sensations: his brain feels turned to lead or his heart as if it were stopping or his intestines abnormally mobile. He cannot think as he did: he does not feel appreciative of friends or affectionate towards relations, his interest in them is diminished or lost. His features are drawn and his expression one of misery. In some cases, the inner ends of the eyebrows are lowered and approximated while the outer are raised. The attitude is one of general flexion, the head bowed, the arms held to the sides and the elbows, wrists

and knees flexed. He adopts a crouching position, like a dog about to be whipped, suggesting an attempt to occupy the smallest possible space. Patients creep, as it were, away from others and into themselves to avoid the shafts of mental and physical misery. Speech is monotonous in tone and matter, the patient reiterating sentences expressing his fears. Such symptoms denote some defect in that faculty of receiving and co-ordinating impressions, internal and external, which in usual circumstances conveys to us the feeling that all is well with our bodies and is known as Kœnæsthesia.

So absorbed may the patient become in his misery that any activity becomes impossible. He does not get up, dress, eat, go to stool or to bed unless assisted or even compelled. Refusal of food is a very troublesome symptom and a very common one. It may be due merely to want of appetite or to some delusion, for instance that the food is poisoned, or he may think he is so impecunious that he cannot afford to pay for what he takes, or he may hold he is unworthy to have food, or he may wish to kill himself by starvation. A suicidal tendency is very common and for purposes of treatment should be held to be present in every case of melancholia. Some patients though wishful to kill themselves cannot, from want of power of will, make the necessary effort; or if it be made, it is half-hearted and not carried to a conclusion. On the other hand, some ponder the details of a more or less elaborate scheme and watch for an opportunity to carry it into effect. Other patients act on the impulse of the moment, not having previously paid much attention to the matter. Self-mutilation is sometimes inflicted. Patients have been known to gouge out their eyes or amputate the genital organs, perhaps as punishment for sins of which they accuse themselves and perhaps from impulse. Homicide is uncommon, but it occasionally happens that, for example, the father of a family kills his wife and children to save them from the effects of some disaster he believes to be impending.

Physical symptoms are numerous. The tongue is generally thickly coated and often dry. The breath is foul. Flatulence is common and constipation the almost invariable rule. Not infrequently the complexion has a slightly icteric tinge, which presumably gave its name to the disease. The gastric juice has been found to be hypertoxic.

The pulse is often slow. It is apt to be very variable in the same patient, sometimes being normal in rate, sometimes too rapid and sometimes too slow. Blood-pressure also varies: it is often higher than might be expected. The extremities are frequently cold and clammy; occasionally purple and œdematous. The blood shows changes of a chlorotic type. The respiration rate is slow and the range of the respiratory excursion diminished. The urine contains a smaller amount of solid matter than normal, and has been found to be hypertoxic. In the female, the catamenia are often suppressed, or at least are very scanty and irregular in time. The sensitiveness of the skin appears to be diminished, and definite areas of anæsthesia and analgesia of so-called functional distribution have been described. The great difficulty of determining degrees of cutaneous sensibility in mental patients has to be borne in mind, and results sometimes vary from day to day. Reflexes are usually sluggish. Muscular force seems to be diminished and a faint tremor may often be observed. The temperature is frequently subnormal. The skin and hair are dry and the latter also brittle.

MELANCHOLIA WITH DELUSIONS

On such clinical phenomena as these may be superimposed delusions. The illness commences, as does simple melancholia, with weariness, irritability, insomnia and vague general uneasiness. These symptoms are followed by fears of some impending evil, disgust at the world or at self, and by sentiments of unworthiness and remorse. The patient carefully examines his past life and not infrequently fastens upon some moral lapse or even upon some absurd peccadillo of childhood as the sin for which he is forsaken by God, is damned, has had his soul destroyed, or for which he is about to be imprisoned, tortured and executed. In other cases, the delusions are of financial ruin and loss of social position. Kænæsthesia may be so diminished that the patient feels as if some part of his body were lost or converted into some lifeless material, or indeed that he is wholly dead. He may suffer from kænæsthetic paræsthesiæ and believe his body is occupied by some animal or devil, or he is turning into an animal. When the delusions become fixed and systematised, as they sometimes do, the disorder resembles delusional insanity. In this state delusions of a most depressing character may coexist with an affective state of comparative cheerfulness, and the patient talks placidly and even with gusto of his miserable condition.

MELANCHOLIA WITH AGITATION

In certain cases of melancholia the reactions of intense grief and of despair are a most marked characteristic. The patient is quite obviously most anxious and agitated. His face expresses terror. There is a monotonous reiteration of gestures of despair and anguish. He groans, exclaims, complains, wrings his hands, twists his fingers and perhaps tears his clothes, plucks out his hair or even rolls on the floor in the extremity of his mental pain. The pulse is usually accelerated.

MELANCHOLIA WITH STUPOR

A very different picture is presented in melancholia with stupor. In this variety there seems to be so entire an absorption in misery that the patient is prevented from movement and paralysed with sorrow or terror. Words seem to make no impression upon him and he appears lost to the world. The face is fixed in an expression of pain and the body generally is inert and immobile. Limbs may be moved by a bystander and tend to remain in the position imposed upon them. The patient does nothing to help himself and is often quite incontinent. The pulse is slow and the extremities cold. Anæsthesia and analgesia are usually present, or at any rate no expression of feeling can be excited by the application of a painful or other stimulus. In the midst of this stuporose inaction there are occasional impulsive outbreaks, as though for a moment the inertia were overcome by an imperative call to action.

Course.—The course of melancholia runs from a few weeks to a year or eighteen months and in some cases to several years. Oscillations in severity in chronic melancholia are not uncommon, and among female patients exacerbations coincide with the catamenial periods, or if these be suppressed with

the times when they would have occurred. Melancholia with agitation is of more rapid onset than the other varieties and shows a greater tendency to chronicity. Melancholia with stupor presents a slower march of symptoms at the onset and is generally of longer duration. More especially in this form, but occasionally also in the others, there occurs a progressive mental enfeeblement and the patient is sooner or later reduced to dementia. Death may occur from starvation, auto-mutilation or suicide, but this is unusual when the patient is under care, and the majority of such cases occur among those whose disorder has passed unnoticed or has been misinterpreted.

Prognosis.—Most cases of melancholia end in recovery, but the prognosis is distinctly less good when the patient is over fifty.

Treatment.—The primary rule in the treatment of the depressed is to take measures to keep them alive. Firstly, they must be constantly and assiduously watched to prevent suicide. The various modes of self-inflicted death by precipitation from heights, cutting instruments of all descriptions, drowning, strangulation, poisoning, suffocation or starvation have to be carefully anticipated and averted. Secondly, the patients must be fed. A depressed patient never takes a sufficiency of food if left to himself, and one of the most exacting duties of a nurse consists in persuading the patient to eat. In most cases, where time permits, this may be done by moral persuasion. If this fail it may be necessary to spoon the food into the patient's mouth, but in cases where the patient will not open his mouth or swallow his food even when placed there, tube-feeding becomes necessary. A large tube passed through the mouth necessitates the use of a gag, which on introduction is apt to chip or to dislocate the teeth if, as may be necessary, force be required. It has the advantage of transmitting coarser food more easily than does the nasal tube, and is less apt to get choked. A well-lubricated nasal tube of smaller calibre passed through the nose is the more usual method. It occasionally finds its way into the larynx, and care should be taken this is not the case before food is passed down it. If the tube be in the larynx the patient coughs and chokes; it should then be partially withdrawn and repassed. The food should consist of milk, 4 pints during the day, and with it as a vehicle, well-beaten eggs, malt extract, somatose, Benger's food, sugar, cream and such other foodstuffs of good nutritive value as will pass the tube. Drugs may be given at the same time. Constipation has to be overcome by aperients or by enemata. Hypnotics may be given for sleeplessness, and careful observations should be instituted to discover the dose and time of administration most suitable for the particular patient. Opium is sometimes of value, and is especially so in melancholia with agitation. The initial dose should be 5 minims of the tinct. opii given every six hours. This is increased by 2 minims until 20 minims are given four times a day. The dosage is then gradually diminished, according to the character of the symptoms, and ultimately stopped. It is desirable that the patient should not know he is taking drugs, as this knowledge may induce delusions of poisoning or lead to endless and pointless controversy with physician and nurses as to their supposed effects. Patients should be confined to bed, preferably in the open air, until they have made very substantial physical progress as indicated by the weight, the pulse-rate, the temperature and the character of the facial expression and complexion. They should then only gradually be promoted to a sofa

and to a little gentle exercise, the amount being regulated by the effect on the mental and physical symptoms. Warm baths are sometimes soothing and promote sleep. It is to be carefully borne in mind that on recovery patients usually remember the details of their illness and of the conduct of those by whom they have been tended. The patient should be removed from the influences of home surroundings and of relations and friends, as they are almost always bad. Whether certification is to be advised or not should depend for the most part on the financial resources of the patient and his friends, and the possibility of providing suitable accommodation and a sufficiency of skilled attendants.

MANIA

Definition.—Mania is the term applied to a mental condition in which there is intense excitement, emotional instability and motor activity.

Ætiology.—A family history of mental or nervous disorder is frequent. The affection is chiefly one of early adult and early middle age. Infections, intoxications, emotional stress, worry and overwork have been regarded as causes. It is, however, likely such cases have in fact been rather of the nature of acute confusional insanity and will pass in the future into that category.

Mania tends to recur in the same individual; the abnormal influences which immediately precede an attack are not known.

Pathology.—In most cases of acute mania which come to autopsy nothing abnormal has been found. In some a slight general hyperæmia has been described and in others such degenerative changes as chromatolysis and fatty and pigmentary deposits in the cortical cells. In old cases of chronic mania thickening of the meninges and shrinking and sclerosis of the convolutions may be found.

Symptoms.—Before the symptoms of mental disorder make their appearance the patient may for some days suffer from lassitude, insomnia, headache, irritability, loss of appetite and constipation, or, on the other hand, maniacal symptoms may arise with great rapidity without warning. In the first case the subjective symptoms give place after a few days to feelings of exhilaration and well-being. The patient becomes talkative and abnormally active both at business and at pleasure. Ideas seem to arise and pass through his mind with extraordinary celerity. The attention is easily attracted and with difficulty held. The memory is enhanced and various present circumstances recall things long forgotten. Ideas are not curbed and directed by the will and that particular form of it called the attention, but follow the line of the automatic associations. It is difficult to understand the connection between the ideas expressed by the patient in speech, and this leads to an impression of complete incoherence. If, however, the ideas be analysed it will be found that there is some relationship between them, not, it is true, such as is regarded as important in health, but connections formed by the similarity of the sound of words, chance recollections of the patient and the influence of ordinarily unconsidered and trifling events going on at the moment. The emotions are very unstable and unrestrained. The patient may be gay, affable and friendly even with those whom in health he would repel. With members of the other sex he is likely rapidly to become amorous.

If his friendliness and love be excessive, so too is his dislike and hatred. With but slight or no provocation he will become abusive, threatening and violent. The emotions are also liable to sudden alteration, and changes from effusive friendliness to extreme anger and the reverse are very striking and characteristic. Egoism and vanity are pronounced. The patient feels himself capable of anything and propounds schemes and inventions of every description and on the most extravagant scale. Restlessness is extreme and the patient is perpetually up and doing. He appears to lose all sense of fatigue and his muscular power seems increased, though sooner or later he will look tired, drawn and haggard. He is incessantly talking and laughing or perhaps singing and shouting. His actions are impulsive and without suicidal intent, though he may bring about his death by some impulsive act. He may throw things about and be destructive of property and dangerous to those around. The patient's dress is usually disordered and in the case of women the disregard of appearance and even of decency is striking. The eyes are bright, the hair often on end, and the expression of the features perpetually altering.

Hallucinations are of rare occurrence and delusions are fleeting and without any systematisation.

The pulse and respiration rates are increased, the former ranging between 90 and 120. In a few cases the temperature is slightly elevated. The appetite, if the patient find time amid his many activities to think of food, is voracious. Constipation is the rule, genital excitement quite common. Among women the menstrual flux is diminished or absent. The secretion of sweat and saliva is increased. Weight is lost, the loss often occurring before the appearance of mental symptoms. Sleep is probably absent or at best very inadequate.

Course.—The course is very variable and ranges from a few days to a year or two, in most cases ending in recovery. Exacerbations and remissions are usual. The symptoms may by degrees abate or terminate as rapidly as they began; or the remissions may gradually become shorter and less severe.

When a mania is about to become chronic the physical state improves, the weight increases, sleep is restored and in women the regularity of menstruation becomes established. There is, in addition, abatement of the mental symptoms, although some degree of confusion may occur, perhaps as evidence of oncoming dementia. In some chronic cases the evanescent delusions of the acute stage tend to become fixed and rather more systematised. The course of subacute mania is similar to that of the acute form but shorter.

Prognosis.—The chances of recovery are best in the first six months, and gradually diminish up to about 2 years; after that amount of time recovery is unlikely.

A variety of mania commonly described is the subacute form or hypomania. The symptoms are similar to those of acute mania but less marked. Imagination is very active. Business, social, scientific or political projects are rapidly developed, much talked of and occur in swift succession. The schemes are of a sweeping character, of large scope and often clever, though generally vitiated by some absurd impracticability which escapes the notice of the patient. His conversation has often a certain brilliance, in part due to the unusual activity of his imagination, in part to the exuberance of his repro-

ductive memory, whereby all sorts of matters long forgotten surge into consciousness, and in part to the absence of that restraint which normally checks the expression of a large proportion of a conversationalist's ideas. Egotism is accentuated. Sensuality is increased and the patient often drinks to excess.

Treatment.—The patient should be isolated, by preference away from home, relations and friends. Efficient means must be taken to prevent him harming himself or others, or making himself a nuisance or ridiculous in public. Bed is the best place for him, and a good nurse will often persuade a patient who at first resolutely declines to go there at all to stay in bed. The bed should, if possible, be in the open air, or at least the room should be thoroughly ventilated, as vitiated air leads to an increase of the patient's excitement. There is usually no difficulty in getting the patient to take food. It should, however, be minced, as bolting the food is common. Prolonged warm baths are sedative. Hypnotic and sedative drugs should be tried one after the other in varying doses, and at different times, till some one is found to produce the desired effect. In certain cases drugs fail altogether. The patient's bowels must receive careful attention and an initial dose of calomel is often desirable.

The patient should be kept in bed until the symptoms of excitement have subsided; 3 months or more are not too much. The time he is at first allowed up should be very short and only gradually increased. An accelerated pulse-rate is a marked indication the patient has been up too long. The resumption of other activities should be gradual and a return to home and the ordinary duties of life only allowed after several months have elapsed since the mental symptoms disappeared.

MANIACAL-DEPRESSIVE INSANITY; CYCLOTHYMIA

There are patients who time after time have attacks of mania or of melancholia, that is, who suffer from periodic insanity. There are others who periodically suffer from mania followed by melancholia or vice versa. In some cases the mania is followed immediately and without break by the melancholia, and in others there is a time of complete health between the two. To those cases where there is no interval between them, and the melancholia is again followed forthwith by mania and this by melancholia in indefinite succession, the term circular insanity has been applied.

So intimate has seemed to some the bond between melancholia and mania that they have denied that the one exists without the other and have asserted that the one is either always followed by the other, with or without interval, or the symptoms of the two are invariably mingled. Both phases are held to be disorders of the affections and to be characterised by defect of some of the higher functions, of those of will, attention and judgment and by the pre-dominance over these of lower level automatic associations.

There are probably but few cases of mania in which, notwithstanding the general feeling of mental and physical exhilaration experienced by the patient, he has not moments of depression indicated by his expression of face or by something he says or does. The occurrence of these evidences of depression has been taken to support the hypothesis of the identity of mania with maniacal-depressive insanity. Moments of exhilaration during melancholia are very rare, while the excitement of depression takes the form of

agitation and suggests a stage of misery even more acute than that of passive suffering.

Ætiology.—A history of heredity of the same disorder or of other mental or nervous affections is common. Maniacal-depressive insanity commences as a rule between 20 and 30 years of age and is rather more frequent in the female than in the male sex. It has been suggested that attacks begin as the consequence of the summation of toxæmic states in a manner analogous to the process which not improbably exists in epilepsy. Other investigators have found reason to suppose maniacal and melancholic attacks to be caused by inadequate nitrogenous excretion. Various other occasional circumstances, such as worry or other emotional stress or states of physical ill-health, have been suggested as having causative relations with the attacks.

Pathology.—No anatomical alterations have constantly been found. Degenerative cortical cellular changes have been described.

Symptoms.—The symptoms of the melancholic phase of maniacal-depressive insanity are those described under Melancholia and the symptoms of the maniacal phase those under Mania.

Course.—When one set of symptoms passes into the other the transition is usually a very gradual one; the symptoms of the mania or melancholia gradually diminish and the symptoms of the next phase gradually develop. Between the phases there may be a normal interval of very varying length; on the other hand, in a few cases, the transition is abrupt. The attacks may last for days or for years, but as a rule extend over a few months. The intervening periods are also very variable and range from days to years. After each attack it may be noticed in many cases that the mental level of the patient is inferior to what it was; on the other hand, no alteration may be apparent. Some cases become chronic in one or other phase. Beginning in early adult age, attacks may recur throughout life; on the other hand, they may cease and the patient remain free from them.

Treatment.—The individual of insane inheritance should be carefully directed to live a particularly hygienic life and so far as possible to avoid the numerous physical and mental stresses which are likely to result in a lowered health standard. The patient who has had an attack should be even more careful, and his weight, general nutrition, appetite, the condition of his bowels and of his sleep should all receive attention. The treatment of the attacks is similar to that set forth in the sections on Mania and Melancholia.

STUPOR

A condition in which for periods varying from days to months there is an absence of the usual signs that the mind is at work. The patient is irresponsive, expressionless, unoccupied and mute, and in some cases so inert that he lies for an indefinite time in any position in which he has been put. Stupor occurs in association with the toxic and exhaustion confusional psychoses, manic-depressive insanity, dementia præcox, epilepsy, general paralysis of the insane, and acute alcoholic and lead poisoning.

CHRONIC HALLUCINATORY PSYCHOSIS

In some persons hallucinations, generally of hearing, but occasionally also of sight and cutaneous sensation, occur as the essential or only symptoms, and last for many years. In time a patient may become so exhausted by being harassed by the hallucinations, or confused by the trains of thought consequent upon them, that secondary symptoms may develop.

MENTAL DISORDERS ASSOCIATED WITH DISEASE OF THE THYROID AND OTHER GLANDS

MYXŒDEMA

Symptoms.—The somatic symptoms are elsewhere described. Mentally, the chief symptom is the torpidity of the mental processes. Perceptions, thoughts, feelings and the reactions to these in conduct, all seem prolonged, and this suggests a degree of hebetude out of proportion to the actual loss of power. In many cases there is, however, some clouding of the faculties and apathy. In a few cases there may be present the symptoms of confusional insanity with agitation, hallucinations and fleeting delusions. If left to itself, myxœdema terminates in advanced mental enfeeblement and somatic cachexia.

Treatment.—Treatment by the administration of a preparation of thyroid gland should be used as in cases of myxœdema without marked mental symptoms. It is as well to begin with small doses and gradually increase them, the guide being the pulse-rate, which should be a little in advance of the normal.

EXOPTHALMIC GOITRE

Symptoms.—Emotional instability is the marked mental characteristic. The patient has an appearance of terror, anger, or both, and is, in fact, irritable, worrying and anxious. Sleep is often bad. Hysteriform functional symptoms may occur from time to time. In some instances mental symptoms of confusional insanity with a variety of hallucinations and fleeting delusions, mania or melancholia, especially of the anxious type, may be encountered. Such symptoms last but a few days or weeks and rarely become chronic. There are cases in which, in the absence of physical signs, such as enlargement of the thyroid and exophthalmos, the cardiovascular and nervous symptoms of Graves' disease are present. We are not yet in a position to affirm that the syndrome is essentially the same as that of exophthalmic goitre, and it is premature to assign it either to the group of the sympathoses or to hyperthyroidism.

Treatment.—Careful attention to general nutrition is of great importance, and both on account of cardiac and nervous symptoms exertion should be limited. Patients are almost always anæmic and emaciated, and with the rectification of these symptoms by a good dietary, containing plenty of milk,

malt and cod-liver oil, tonics and rest and fresh air, considerable improvement may result. The serum and milk of dethyroidised goats is perhaps occasionally of service. Surgical operations with excision of part of the thyroid or tying of its arteries are sometimes useful. Carefully regulated doses of X-rays applied over the gland are often followed by excellent results. Symptoms often occur in those who are anxious, and an investigation of the mental state, with an attempt to abolish or diminish the causes contributing to anxiety, may be cautiously attempted.

PITUITARY GLAND

Besides the somatic symptoms of acromegaly, gigantism and alteration in sugar excretion associated with changes in various parts of this gland, mental symptoms of confusion and melancholia, with or without delusions, have been observed.

SUPRARENAL AND GENITAL GLANDS

As well as the symptoms of Addison's disease, there may be mental symptoms of torpor, abulia, inertia and depression. Absence of the testicles in the male or impairment of their functions at the beginning of life results in certain well-known characteristics physical and mental. It is probable the same sort of change occurs in the female, but in her case the difficulty lies in knowing when the defect really exists. The eunuch does not exhibit positive feminine traits of character, but fails in complete masculine development. The same seems to be the case in the female. Human beings without sexual glands, whether they be called male or female, are, as far as generalisation may be permitted, of similar character. Changes of bodily and mental characteristics after castration in adult life are less marked, but such as they are tend to take place in a similar direction. The effect of genital glands on nervous and mental states may, perhaps, be seen in the evidence advanced by some of the effect of testicular and ovarian substances in the treatment of various functional disorders. It at least seems not improbable that such effects are seen in their biological aspect at puberty and at the climacteric.

DISORDERS ASSOCIATED WITH THE SEXUAL LIFE; EPOCHAL INSANITY

Epochal insanity, as here described, has reference to mental disorders whose incidence is specially noticeable at certain times of life, the time of puberty, menstruation or at the climacteric. The symptoms of such insanities are for the most part fundamentally those of syndromes elsewhere described, such, for instance, as confusional insanity, mania or delusional insanity.

PUBERTY

Definition.—Puberty or the time of most noticeable development of sexuality, in its primary and secondary characteristics of elementary somatic appetite and mental alteration, extends over a period of some years, roughly

between 12 and 20 years of age. In some persons the process appears to begin earlier and in some later. In some the evolution is so slow as to be scarcely noticeable, and in others it is rapid. In some the accretion of fresh feelings and ideas scarcely alters the general character of the individual, in others it transforms it into something quite different from what it was before.

Ætiology.—A history of mental and nervous ill-health is frequent in the families of those showing mental symptoms at puberty. Accident, infective disorders, overwork, too great physical exertion and masturbation have all been suggested as possible causes, and certainly it may be that any one of these acting upon a weakly disposition may prove to be a stress too great for the nervous system to bear. It is possible that in this, as in other disorders, the internal secretions may be too small or too great in quantity or improper in quality or may fail harmoniously to co-operate with internal secretions of other glands. Psychic maldevelopment is obvious in many cases and in others can be discovered on investigation; it may often be traced to its source in faulty home environment or to some ill-balanced method of education.

Symptoms.—In some persons, the usual mental changes are exaggerated to a degree suggesting morbidity, while in others, positive mental symptoms make their appearance. With a mere exaggeration, there may be an affective tone of sadness with apprehensions as to the burden of the future, shyness, avoidance of society or moroseness. Feelings indicated by such expressions as "Nobody understands me" or "If only I could get away" are frequent. Reticence, dissimulation and untruthfulness may become noticeable, and may be described as defensive reactions tending to repel uncongenial intrusions upon the individual's domain of his own personality. Between these states and more definitely morbid mental syndromes may be noted "borderland" phenomena, such as neurastheniform symptoms, not infrequently associated with masturbation: hypochondriacal fears especially related to the genital organs; obsessions of scrupulosity in religious and sexual matters; delinquencies of conduct, such as cruelty to animals or to weaker human beings, theft, running away from home or school, or sexual misconduct and functional nervous disorders of the hysterical form. Among more definite mental syndromes may be mentioned alternating restlessness and passivity, amounting in some cases to stupor, stereotyped actions, verbigeration or the long-continued reiteration of words and phrases, cataleptic attitudes and negativism, suggesting very strongly hebephrenic or catatonic forms of dementia præcox; obfuscation, confusion, erotism and religiosity with terrifying visual hallucinations of animals, ghosts and devils and impulsive reactions, suggesting confusional insanity; hysterical insanity; mania and melancholia or combinations thereof.

Treatment.—The preventive treatment of these states is most important and is seldom employed. Parents themselves unconsciously react defensively and are apt to thrust any evidence of neuropathic taint in the family into the background, or at any rate to ignore it. Such parents are apt to present characteristics which scarcely fit them to be successful educators of neurotic children. Where possible, education should be carried on under medical supervision or by those who know something of the particular difficulties of these cases. General hygiene, including the prescription of proper amounts of sleep, rest, exercise, mental work and food, should receive careful atten-

tion and the effect of mental and physical exertion be assiduously watched. A sympathetic insight into the child's mind is of importance, and he should be encouraged to carry his difficulties, often of a sexual character, to the proper quarter for explanation and advice. In some instances change of scene and companionship are most useful. Where actual disorder occurs, attention to general health and cessation of mental work are imperative. In many cases a period of rest in bed is indicated. Attention to the amount and character of the food and to the action of the bowels is always important. Symptoms must be treated according to their character. Analytic investigation of the patient's mental make-up may be of immense help.

MENSTRUATION

Ætiology.—Symptoms are more likely to occur in those predisposed by heredity or by the possession of a nervous diathesis than in others. What precisely may be the process by which the nervous system is affected by menstruation is unknown, but here, as elsewhere, auto-intoxication has been suggested. It has been supposed that by the flux a toxin is eliminated; and if the eliminating process be in some way imperfect, the retention of the poison may produce symptoms. In support of this hypothesis it has been found the toxicity of the serum of the blood is increased just before the commencement of the catamenial period. An upset of endocrine balance should be remembered as a possible cause.

Symptoms.—Some alteration of mental characteristics may be observed in a certain number of women at the times of the menstrual flux. There may be merely a slight degree of heightened sensitiveness, irritability, capriciousness or apathy; or quite a marked alteration of affective tone with depression or, on the other hand, with excitement, restlessness and loquacity. When still more pronounced, functional nervous disorders of an hysterical type may occur with some degree of confusion, impulsiveness or obsessions with strong tendencies to alcoholism, sexual satisfaction, theft or suicide. So severe, in rare instances, may the symptoms become, that the attack may properly be called one of confusional insanity. Hallucinations may arise, while genital excitement may be intense. In some cases, instead of the usual agitated and restless reactions of the confusional state, there may be stupor. Symptoms, whether pronounced or not, commence as the time for the appearance of the flux draws near, and last for an indefinite time during the flow or after it has ceased; in some instances, with its appearance the symptoms abate. If there has been any confusion, the patient has subsequently a very indefinite notion of what occurred. Even in cases of amenorrhœa nervous or mental symptoms may obtrude themselves at the periods when the flux should have appeared. It should be remembered in any mental disorder, especially if acute, that symptoms are usually more pronounced during the catamenia and for a few days before and after the flow, or if there be amenorrhœa, at the times when the catamenia should have begun.

Treatment.—The only known way to combat these evils lies in endeavours to raise the general health standard. Constipation is exceedingly common, and is also the most usual local cause of menstrual disturbance. Measures against it may be adopted even in the presence of a denial of its existence, for it is astonishing how many women are found to be constipated who allege

a regular action of the bowels. The question of food is also important, and it is again surprising how many women maintain that their absurdly small intake is sufficient. Rest at about the time the period is expected is of great importance, and small doses of bromide, for instance gr. v, three or four times a day, are most useful. Some have found ovarian substance of value. Remembering that even the severest symptoms are usually only of a few days' duration, arrangements may be made for the treatment of the patient at home.

MENOPAUSE

Mental symptoms, sometimes of a severe character, may be associated with the menopause. This process of involution, indicating the termination of the individual's biological function of child-bearing, appears, in the predisposed, to be even more of a strain than the process of evolution associated with puberty. It may perhaps be supposed that the stress is now upon an organism less able to bear up against it. Certainly, in many instances, the excessive loss of blood must in itself be a cause sufficiently exhausting to produce nervous and mental symptoms. Auto-intoxication has in this case also been advanced as an explanation of the condition.

Symptoms.—Symptoms are as a rule those associated with exhaustion. Headache, backache, feelings of weariness induced by but a slight amount of exertion or even by none at all, depression and irritability, are almost the natural accompaniments of the menopause. Hypochondria, jealousy, various unreasonable apprehensions, obsessions, devotional excess, erotism and even obscenity of conduct have all been noted. Melancholia and confusional insanity may be quite definitely present, while delusional insanity with hallucinations of genital sensations suggesting assault, rape and pregnancy may commence at this time.

Course.—The course of the symptoms, if slight, or if those of confusional insanity, is of some months' duration and terminates in cure. If the symptoms be those of melancholia, the course is likely to be longer and may become chronic, while if they be those of delusional insanity, chronicity may almost certainly be expected.

Treatment.—Treatment should be directed towards the prevention of excessive hæmorrhage and the mitigation of the exhaustion which may ensue upon it. Plenty of good food, rest and sleep are of great importance. Removal from home surroundings is generally desirable.

DISORDERS ASSOCIATED WITH CHILD-BEARING

Mental disorders may occur during pregnancy, at or shortly after parturition, and during lactation.

DISORDERS OF PREGNANCY

Ætiology.—A family history of nervous and mental disorders, of alcoholism or of epilepsy, is frequent. In some instances the mothers of patients have suffered in a precisely similar way. In the personal history of the patient albuminuria, alcoholism or other intoxication, emotional shock, worry and overwork may appear as possible causes. The incidence

is greater upon primiparæ, upon the unmarried and upon women over 30 than upon others. Some women seem to have an inexplicable idiosyncrasy for mental breakdown in connection with child-bearing. In one class of case, there seems no predisposition by heredity or otherwise and the cause would appear to lie in the pregnancy itself or in some condition such as emotional stress, overwork or a toxic or infective state occurring during it. In another class of case, predisposition is marked, intoxication, infection or circumstances of an exhausting nature are absent or not plainly present, and the affection may be regarded as one occurring in a predisposed person and excited by the pregnancy.

Symptoms.—That pregnancy is a time of nervous instability is well known, and many women while in this state exhibit irritability, impulsivity, religious or sexual excitability, or absurd and extravagant tastes and desires entirely foreign to them at other times. More pronounced mental symptoms are, however, present in some cases. Where there seems to be no predisposition the symptoms are those of confusional insanity. Sleeplessness generally precedes the more acute symptoms, which consist of restlessness, agitation, anxiety, loss of bearings in space and time, and hallucinations, sometimes pleasing and sometimes terrifying. Conduct may be violent or sexually licentious, or both. Such symptoms vary in intensity and length of duration and sometimes get better before or at parturition. Where predisposition is marked, the symptoms may be those of mania, melancholia or a mixture of both. The melancholia is usually of the simple type, but may occasionally be of the delusional kind with delusions of ruin, of unworthiness, sinfulness, jealousy or love. These symptoms have a march which seems independent of the pregnancy, and which lasts beyond it.

Treatment.—Treatment of cases due to exhaustion, infection or intoxication consists in elimination or neutralisation of the cause and in regulation of sleep, rest, food and the bowels. The treatment of cases not apparently due to such causes can only be symptomatic. The problem as to the desirability of artificially terminating the pregnancy may have to be faced, and its solution must depend upon the physical state of the patient and the extent to which the pregnancy may be regarded as an essential and continuing cause of the mental disorder.

MENTAL DISORDERS OF PARTURITION AND THE PUERPERIUM

Symptoms.—The symptoms of excitement occurring immediately before or during parturition as a rule pass away when the child is born. More rarely they persist for some weeks. A more common variety of puerperal insanity commences in the second week after parturition. The temperature rises, the skin becomes dry and hot, the pulse rapid, the bowels constipated, the tongue furred, the lips dry and the eyes bright. The patient complains of headache and of feeling ill. The lochia may become foul, with local manifestations of infection. The urine often contains albumin, while the amount of urea is diminished. Agitation, anxiety and restlessness soon appear, and are associated with varying degrees of confusion, amounting even in some cases to acute delirium. Hallucinations are often present. The symptoms of cases in which there is no local infection and in which exhaustion from loss of blood or from the general strain of parturition appears

to be the exciting cause are precisely the same, save that fever and other such signs of infection are not present.

Course.—The above symptoms may last a few weeks, or even months, and then gradually pass off or leave the patient stuporose for a further period. Occasionally death occurs from the severity of the toxæmia or from exhaustion, and at times the symptoms become chronic and in a few cases suggest dementia præcox of the catatonic type.

Treatment.—In the cases of initial excitement labour should be expedited under chloroform and sedative measures adopted. In cases due to toxæmia the essential treatment is that of the toxic focus, and to place the patient in the best possible position to resist the action of the toxins. In cases due to exhaustion, measures should be taken such as those suggested in the treatment of the exhaustion psychoses.

INSANITY OF LACTATION

Symptoms of mental disorder occurring during the period of suckling are almost always due to exhaustion, when feeding has been carried on too long or because the patient was not fit to undertake the work in the first instance or owing to lack of sufficient nourishment. The symptoms are those of confusion, either with or without hallucinations. The patient may show an aversion for her child, and precautions should be taken against both infanticide and suicide. The physical state is one of asthenia and there is probably much loss of weight.

Course.—The course is rather more prolonged than in puerperal insanity and proportionately rather fewer cases get better.

DEMENTIA PRÆCOX; ADOLESCENT INSANITY; SCHIZOPHRENIA; FOLIE DISCORDANTE

Definition.—A mental disorder commencing in a large majority of cases during juvenility and early adult life; sometimes running a regularly progressive course and sometimes irregularly with exacerbations and remissions; whose most salient symptoms are a diminution of the emotions and will, and which, as a rule, terminates in general mental enfeeblement.

Ætiology.—The symptoms of dementia præcox most usually first make their appearance between 15 and 30 years of age. They may, however, appear much earlier, about the beginning of the second dentition; or much later, at the time of the menopause. The adjective præcox must not, therefore, be taken to imply that the disorder is one only occurring at a period of life when dementia might be regarded as precocious in its appearance. It affects both sexes equally.

A family history of dementia præcox or of other sorts of mental and nervous diseases is common. In some instances the disorder affects several members of the same generation. If dementia præcox be likened to such an affection as, for instance, Friedreich's disease, it might be regarded as a developmental failure; for this view anatomical evidence has been brought

forward. But whether or not there is an initial weakness or mal-arrangement of the neurons, occasional events, such as infections, auto-intoxications, emotional shocks, excesses in intellectual work, masturbation and venery have in many cases immediately preceded the first appearance of the symptoms of the disease. The internal secretions of testicles or ovaries, regarded as defective or excessive in amount or abnormal in quality, have been suspected to have an influence in its production; and, on the other hand, regardless of somatic influences or structural peculiarities, the guilt has been laid at the door of emotionally toned groups of ideas, named complexes, mostly, if not entirely, of sexual origin, forced out of consciousness by a process of repression, and in this abnormal situation exercising an influence sometimes productive of symptoms of psychasthenia, sometimes of hysteria and sometimes of dementia præcox. The trend of thought of patients suffering from dementia præcox seems to be of a particularly introspective character. A process similar to day-dreaming goes on, but is carried to excess along abnormal lines. By a diminished interest in the environment and by the development in its place of a world of phantasy, refuge would appear to be instinctively sought from the conflicts and failures of actual life.

Pathology.—Macroscopically pachymeningitis, congestion and exudation have been described. Often there are no abnormal naked-eye appearances. Degenerative changes in the cortical cells, as swelling, dislocation and atrophy of the nuclei, chromatolysis, fatty and pigmentary degeneration of the cell-bodies are usual, especially in the case of the cells of the deeper layers. Quantitatively the cells are reduced. The cell processes forming the association fibres exhibit degenerative changes: the neuroglia is increased. These appearances are occasionally associated with vascular alterations, and may then possibly be regarded as secondary to an inflammatory or toxic process; but, on the other hand, the vascular system may be quite normal, and the appearances may then suggest a primary neuronc degeneration. Similar lesions of the cerebellum and spinal cord have been described. The testicles show an increase of interstitial tissue, shrinking of the tubules and diminution of the spermatogenic cells. Analogous changes are found in the ovaries.

Basal metabolism has been found to be reduced by about a quarter in half the cases of dementia præcox examined from this point of view.

Symptoms.—The childhood of patients is often, from a medical point of view, quite uneventful. On the other hand, there may have been unusual brilliance and precocity, either general or of some particular faculty, or the child may have been reserved or shown some special characteristic, as excessive or defective emotionalism.

Symptoms as a rule develop very insidiously, and are very likely to be attributed to laziness and want of goodwill rather than to disease. The patient's power of attention seems to fail, intellectual effort becomes difficult, there is a lack of interest in things formerly entertaining, and this is especially noticeable in a diminishing display of affection or a hostile note in his attitude towards members of his family. Variations of humour of inadequate causation are frequent, the patient being inordinately angry or pleased about trifles; sometimes he is absurdly obstinate and sometimes absurdly docile. Purposeless laughter or crying, the continuous reiteration of certain words or phrases, grimacing, mannerisms and extravagant behaviour suggesting

a desire to attract attention or to be humorous ; leaving home and wandering from place to place for no reason or for some very silly one ; the expression of ideas of grandiosity, persecution or religious extravagance, or assaults on others or attempts at suicide on absurd grounds, are all symptoms which may definitely draw attention to the patient's mental condition. In other cases the disease may have a far more rapid onset with neurastheniform or hysterical symptoms, or with those of mania, melancholia or confusion. In any case, with the disordered conduct and with the expression of morbid notions, there will probably be found the somatic symptoms of anorexia, constipation, loss of weight, anæmia, headache, insomnia and occasionally elevation of temperature.

Hysteriform and epileptiform convulsions are not uncommon in the early stages. In some cases apoplectiform seizures with subsequent aphasia and hemiplegia occur. The palsies are, as a rule, transient and in this respect resemble those of general paralysis of the insane. In a few rare cases, such seizures have been the first symptoms of the disease.

Physical signs are often, but not invariably present. General sensibility and that of the special senses often appear diminished, though it always remains doubtful whether patients do not in fact feel quite acutely, though psychic inhibition prevents them from showing that they feel. The mechanical excitability of the muscles and nerves is sometimes increased. The tendon reflexes are usually increased and the cutaneous diminished. In catatonia, and occasionally in other forms, muscular rigidity is present. The pupils are usually dilated and sometimes display a transient irregularity and deformity of contour : they are not infrequently sluggish in their reaction to various degrees of light and to other nervous and mental influences. The paradoxical reflex to light may be present. Cyanosis and coldness of the extremities are common. Edema of the dorsa of the hands and feet and of the cheeks is sometimes found. Over the œdematous areas there may be superficial erosions. Dermographism has occasionally been observed. The pulse-rate is variable, sometimes low, sometimes high and sometimes alternately high and low. The blood presents the appearances of a chlorotic type of anæmia so far as the red corpuscles are concerned. In the acute stages there is a moderate leucocytosis, the increase being chiefly in the polymorphonuclear and the large mononuclear corpuscles. With an approach to recovery the blood count tends to approximate to the normal. In stuporose states a lymphocytosis and an increase of eosinophil cells occur. In females the menstrual flux is suppressed or at any rate irregular. The menopause occurs early. The quantity of urine is slightly diminished. The excretion of chlorides is increased, of phosphates remains normal and of urea is diminished. Albumin is sometimes found. The excretion of methylene-blue is retarded.

HEBEPHRENIA

Definition.—Etymologically the term means the insanity of youth and is expressive of nothing else than adolescent insanity. There are, however, varieties of dementia præcox, and hebephrenia is conventionally used as the name of one of them.

Symptoms.—Symptoms commence in the majority of cases during juven-

ility or early adult life and in a small number of cases in childhood and middle age. The onset may be by scarcely perceptible stages, the patient slowly becoming idle, obstinate and indifferent and displaying symptoms of general ill-health and failure in nutrition. On the other hand, the earlier symptoms may simulate those of hysteria. As the disorder progresses, symptoms of confusion develop and the patient's ideas of his relationship with time and space become muddled. He may by word or action express delusions alike absurd, puerile, vague, transitory and not systematised. These may concern his body which he believes to be changed in some way; or his personality has become altered; or they may be persuasions that he is guilty of some crime, persecuted, or is wealthy and of importance, or may turn upon religious or sexual matters. Masturbation is commonly practised with great frequency and, if possible, unrestrained intercourse with the other sex is obtained. Hallucinations are frequent. The result of the delusions, the hallucinations and the confusion may be seen in restlessness and agitation. With such symptoms there may also occur grimaces, attitudinisation, mannerisms, the frequent performance of some apparently purposeless movement or series of movements, the constant repetition of words and sentences, senseless laughter, impulsive violence and emotional emptiness which in general characterise dementia præcox and which in part differentiate hebephrenia from confusional insanity occurring in young persons. The suggestibility, stereotypy and negativism which will be dealt with under catatonia may also be present in hebephrenia. Symptoms such as these may last for years or may in some cases remit or intermit. As time goes on the patient appears to get more and more demented, loses touch with the outside world and lives the mere passive life of the vegetable rather than the more active one of the animal. The degree of dementia as estimated by loss of memory and power of ideation is difficult to estimate, since from time to time the patient may show signs of an intelligence whose existence would otherwise scarcely be suspected. The mental faculties passing under the names of affectivity, appetency and will do not, however, after the earliest stages give evidence, even occasionally, of their existence. It is because of this peculiar and partial incidence upon the mental functions that the terms "*folie discordante*" and "*schizophrenia*" have been suggested as appellations alternative to dementia præcox. Some authorities describe a "simple" form of dementia præcox and mean thereby a condition in which there is a slow decline of capacity, commencing at the time of juvenility, and not marked by the more striking symptoms of mental disorder described under the above heading of hebephrenia.

CATATONIA

Symptoms.—This variety of dementia præcox may commence in the same ways as hebephrenia, or occasionally with stupor or one or more of the symptoms now to be described or, more frequently, with such symptoms conjoined with those described as peculiarly characteristic of hebephrenia.

One of the most striking of these symptoms is negativism. In this there is what appears to be a pig-headed opposition to actions suggested to the patient for performance. He declines to get up from or to go to bed; to dress or to undress; to eat or indeed to do anything unless he is compelled by

superior force. This resistive attitude extends in some cases to an opposition to the patient's own needs—for instance, he will not go to stool, or pass water, even though such actions would appear imperative. As a further extension of this attitude the patient will sometimes not only decline to carry out what is required of him but proceeds to do the exact opposite. As an explanation it has been suggested that negativism is a defensive measure on the part of the patient to hinder the operation of an external influence upon his own personality. The next most pronounced symptom is suggestibility. This may or may not be curiously mixed with negativism, though superficially the two states are very different. In it there is a tendency to accept and to act upon any suggestion coming from without. Patients are slavishly obedient. The limbs are as pliable as wax and preserve any attitude imposed upon them. Movements seen, or noises heard by patients, suggest imitation and they will adopt the poses or movements of those about them (echopraxia) or repeat words and sentences (echolalia). It may, however, be noted that it is only the suggestion to perform more or less futile or indifferent actions which is accepted. Suggestions to carry on useful lines of conduct are ignored. Stereotypy is another common symptom, and patients will take up some attitude, or repeat some movement, word or sentence perhaps for hours together.

In bed a catatonia patient may lie tightly curled up or on the flat of the back with limbs rigidly extended and the head uncomfortably raised from the pillow. When up, the patient remains in some one attitude, kneeling or standing on one leg, or on tiptoe, or he sits on a chair in an odd or uncomfortable-looking attitude with his arms in some favourite position, perhaps of contortion, and his face set in an expression of fatuous pleasure or depression or contempt. If the patient walk it will probably be up and down a short length of ground or round a small circle and perhaps with an odd mannerism of gait. He may walk on his toes, or on his heels, or effect progress by a series of hops, by alternate long and short steps or by a step something like that of a polka. If asked to shake hands, he will do it with a sort of diffidence, without an answering pressure, the elbow being kept to the side and the hand and fingers extended. If the patient says anything at all, he will probably repeat words and sentences which seem to have no reference whatever to the actualities of his situation (verbigeration). He may invent neologisms, or words composed of the senseless juxtaposition of the syllables of words really in use. At times the patient is quite mute for months or years. The handwriting is often strange and affected. Flourishes and hieroglyphics are frequent. Words and sentences are repeated and underlined. In a few rare cases the letters are so formed that the writing can only be read in a mirror. The written matter is often surprisingly good, and does not indicate such a degree of mental deterioration as might be expected from the patient's general conduct. If asked for an explanation of their oddities patients often cannot account for them or state they are compelled to perform them. Emotional indifference or apathy, absence of feeling for relations and friends, for propriety and decency, diminution of spontaneous and voluntary attention, and absence of will coexist in the early stages, and often for years, with a high degree of intelligence and with intact memory. After some considerable time, perhaps amounting to many years, the appearance of dementia is more established and the capacity for intel-

lectual effort and memory of reproduction seem seriously diminished or indeed abolished.

Course.—The course of catatonia is a long one. Patients may continue in the same state for years. At times symptoms abate and the patient seems to wake up. His memory of conservation and his intelligence may be found during a remission not to have been impaired. There are in catatonia occasional phases of agitation and with them an increase of grimaces, absurd actions and verbigeration. Occasionally there may be impulsive destructiveness or violence.

PARANOID FORM

This form commences at the same time of life as the other two or perhaps a little later.

Symptoms.—The onset is rapid, and the delusions which are a marked feature and give this variety its name, at once attract attention. They may be hypochondriacal, perhaps with ideas of bodily change into some foreign substance, or into some animal, of persecution, sinfulness, financial ruin or grandeur. They are generally accompanied by hallucinations of the various special senses. The delusions are more fixed than those met with in hebephrenia and tend to systematisation, but they are not so fixed or so systematised as those of chronic delusional insanity. At first, the delusions and hallucinations produce agitation, depression, exhilaration or a trance-like state and, according to the dominating idea of the moment, the patient will probably conduct himself with arrogance, shrinking timidity, or with suggestive coyness or as if in ecstasy, but emotional activity soon passes and leaves behind indifference. At this stage, or earlier, such evidences of automatism as stereotypy, verbigeration, grimacing and mannerism will appear. Dementia ensues after a very varying period.

Course.—Dementia præcox may begin with symptoms of one type and during its course those of another may develop. The advance in the severity of symptoms may be very gradual, without remission or marked exacerbation, or it may be rapid. In some cases, notable exacerbations are frequent and are followed by remissions, in each of which the patient is found to occupy a lower intellectual level than before. Whether gradually or after many exacerbations, the patient eventually arrives at a condition of apparently profound dementia, in which, however, there may appear from time to time evidences of a degree of memory and intelligence which suggest that the dementia is more apparent than real. Often after the subsidence of the more acute symptoms, the patient is found capable of some useful though humble employment. In other cases, the abatement of the severity of the symptoms is very great, and indeed total disappearance of symptoms is not unknown. The term "dementia" in the title of the affection must therefore not be taken to mean that dementia is a necessary part of the disorder, or that the appearance of dementia always corresponds to real mental extinction.

Treatment.—Where a child is known to be predisposed by heredity and his character or mental equipment is abnormal in some way, particular care should be taken over his education. Overwork, physical or mental, emotional excitement and the infections should be assiduously avoided, and the education of character such as to prevent the development of self-absorption,

vanity and introspection and to promote self-control and unselfishness. On the appearance of pronounced symptoms, or earlier if possible, the patient should be put to bed and every effort made to improve the general health. The amount of food taken, the action of the bowels, the weight, and the length and quality of sleep are all most important matters to which attention should be paid. Food should be ample and of high nutritive value. Rest, diathermy and strychnine appear to raise the rate of basal metabolism. It is well, however, to be cautious in the administration of strychnine if the patient is at all excited. Purgatives or aperients should at first be regularly given and until there is no doubt that the constipation, which almost invariably exists, has been relieved. No reliance should be placed on the patient's reports as to the bowels, and the dejecta should be inspected. If the sleep be poor, hypnotics should be given, not with unthinking routine, but they and the dosage should be varied, and by experiment the minimum necessary dose which best suits the patient discovered. So far as possible, the patient should spend his time in the open air, his couch or bed being arranged in a garden, on a veranda or near an open window. Attempts at suicide, though infrequent, should be prevented by constant watching and the removal of everything the patient might use as a weapon against himself. If his bed be near a window on any but the ground floor, arrangements must be made to hinder him from throwing himself from it, and for this purpose light wire netting may be used. The length of time the patient is kept in bed should depend on the progress made, but at least no harm will be done if he stay there for months. If improvement be obtained, convalescence should be prolonged and the patient only gradually permitted to increase his activities. At this stage, occupation therapy may be commenced, and consists in getting the patient to learn some handicraft—for instance, sewing, knitting, basket-work, rug-making, modelling, gardening, or carpentry. In this way the emptiness of life, so marked a feature in the institution career of chronic patients, may be mitigated. In contrasting the condition of patients suffering from dementia præcox upon whom constant individual attention cannot be bestowed with that of those who are more fortunate and have had the advantage of the guardianship of a good and wise nurse to themselves, it is difficult to avoid the conclusion that skilled individual attention has an enormous therapeutic influence. Patients so circumstanced can often, by the psycho-therapeutic influence of a healthy mind properly applied, be restored to at least a considerable degree of mental health and can be kept at that level. Unfortunately, few can afford such attention, while on the other hand a sufficiency of the qualities of patience, charity, knowledge and skill required in the nurse is rarely present in any one individual. The pity of a diagnosis of dementia præcox lies in the therapeutic hopelessness at once engendered thereby. Nevertheless, experience teaches that treatment on the lines above suggested does much to stay progress towards that mental degradation which too frequently is regarded with fatalistic resignation.

The treatment of patients by the induction of malaria has been attempted, and in some cases temporary improvement has followed. The results, however, have been less encouraging than similar treatment in cases of general paralysis of the insane.

When dementia has apparently definitely set in, the somatic functions should

still be watched and regulated and attempts should be made to make use of such mental activity as may still be left.

Paraphrenia.—Of late years the term *paraphrenia* has been introduced to indicate a mental disorder having resemblances, on the one hand, to paranoid dementia præcox and, on the other, to paranoia. During the early stages of paraphrenia it is impossible to distinguish between it and paranoia, but later on exaltation of self with delusions of grandeur are more markedly a feature of paranoia than of paraphrenia. The paranoid patient is, however, less aggravated and influenced by delusions of persecution than is the paraphreniac; is somewhat more reasonable and controlled in his dealings with those he holds to be his persecutors and enemies; and tends rather to halt at a certain stage in the development of his disorder than to pass, as does the paraphreniac, through increasingly extraordinary delusions and hallucinations to dementia. The paraphreniac, in contrast to the patient suffering from paranoid dementia præcox, does not show the emotional vacuity which is so marked a feature in the latter.

The distinction in practice between paranoia, paraphrenia and paranoid dementia præcox is often of extreme tenuity; nor do descriptions found in literature present anything like clear pictures of decidedly separate morbid entities. It is perhaps for this reason that the conception of paraphrenia has met with less acceptance in this country than abroad.

DELUSIONAL INSANITY

Delusional insanity or paranoia is an affection in which delusions, generally of very gradual growth, persist for long periods, usually until death or the patient's mental extinction in dementia.

Ætiology.—In many cases, but by no means in all, there is a family history of mental or nervous disorder. The age at which symptoms manifest themselves for the first time is, as a rule, early middle life. Usually they appear quite insidiously, but occasionally seem to date from some bodily or mental stress. Some find the cause of paranoia in reaction against inadmissible phantasies, the resulting self-accusation being diverted from the self and fastened upon others. Marked delusions occur in some cases of senility, but are not so fixed nor are they systematised in the same way.

Pathology.—In cases of long standing in which dementia has occurred the brain shows degenerative changes. In many cases nothing of a morbid character has been found.

Symptoms.—The basic mental characteristics of the patient, shared with many persons who do not become more pronouncedly morbid, are touchiness, a tendency to see in the words and conduct of others endeavours to slight him, suspicion, reserve and no small degree of vanity. Persons exhibiting these peculiarities are commonly enough met with in the ordinary business of life, and a certain few of them are recognised as eccentric, without being regarded as insane. In those about to suffer from delusions, these characteristics slowly become more marked. Whether as a result of illness or worry, or of those disappointments which are so common in early middle life and which blunt the edge of earlier hopes, or quite independently of any obvious cause, the patient develops vague feelings of something being amiss.

In seeking for an explanation, he may decide the feelings are due to some disorder of his alimentary or genital or other system, and a hypochondriacal turn may thus be given to his mental twist; or, on the other hand, he may be suspicious that his relations with society, or with some group of society, or with some particular individual, have become warped through the agency of some one who owes him a grudge or has a mischievous and inexplicable desire to do him an injury. The patient becomes at once both more introspective and watchful of the behaviour of those with whom he comes in contact. He analyses what they do and say, and sees in trivial acts and words a meaning having reference to himself. People, he supposes, point at him or look at him with contempt, or smile as he passes or whisper to each other about him. To avoid these annoyances, the patient may frequently change his residence, or leave home and wander from place to place, seclude himself or complain to the police. At this stage the vague feeling of being worried and annoyed by some one or other, who may be no more closely defined than as "one" or as "they," becomes a more definite delusion of persecution by some body of persons, as, for example, "the secret police" or the Jesuits, or some one person upon whom the patient fastens as the author of his wrongs. Patients' explanations of these fancies are often very ingenious, and such skill do they sometimes display that the detection of flaws in their arguments is most difficult. Not infrequently they induce others to regard them as real martyrs. In most cases, hallucinations of hearing, taste, smell and general sensibility now develop, hallucinations of sight being extremely rare. The patient hears the voices of his enemies insulting him, the sound of their voices being conveyed to him in extraordinary ways, perhaps, for example, by wireless telephones. He may allege persons climb up to his windows at night, or hide themselves in the ceiling, for the sole purpose of worrying him with their insulting or obscene remarks. Some patients stuff their ears with cotton-wool to avoid hearing such voices. At times patients complain their minds are read and their most intimate thoughts are repeated aloud or that they are compelled to say words and sentences, usually obscene, put into their mouths against their will. Such a symptom goes by the name of a "psycho-motor" hallucination. Hallucinations of smell and taste are employed by the patient to demonstrate that his food is poisoned or an endeavour being made to kill him with noxious fumes. Hallucinations of general sensibility suggest to the patient he is being electrified or acted upon by some mysterious agency. Hallucinations in connection with the genital organs are frequent, and patients complain they are sexually assaulted or their organs are tampered with, perhaps with a view to rendering them impotent. They frequently invent words which they think descriptive of their state or of what they think is being done to them, and which consist of a curious medley of syllables derived from scientific terms. For instance, a patient may allege that he is being "tortified" or "telepathrayed." Having decided who are their enemies and the modes by which they are persecuted, patients proceed to defend themselves, sometimes by flight and concealment and sometimes by the radical method of homicidal assault. This class of patient is the most dangerous of all. He has perhaps effectually concealed his disorder or at the least has avoided certification, has waited his opportunity and has cleverly elaborated the proposed attack. They are not as a rule suicidal, though some have been

known to kill themselves to avoid persecution, and some others with a view to putting their persecutors in the wrong. At a later stage the patient's ideas as to his personality become changed in a grandiose direction. He opines his position in the social order has immensely improved, and he puts forward pretensions he is a king, or his wealth is enormous, or he has gathered up all power and wealth into his hands and is a god. Some explain this transition as a sequence of the ideas of persecution, the patient imagining that one so much persecuted and thought about as himself must necessarily be some one of very considerable importance. As time goes on the hallucinations appear to become less well defined. The patient may continue to talk of his wrongs and the tortures which are inflicted upon him, but he appears to do this as a habit and to take them as a matter of course.

Course.—It remains a moot point whether or not delusional insanity always terminates in dementia. In many cases, intelligence of a high order remains for many years, and in its possession the patient dies of some physical disorder. In others, there arises a slowly progressive deterioration, and this is perhaps more likely to occur in those cases in which symptoms appear earlier than is usual and in which systematisation is not much elaborated. In any case the course of the affection is very prolonged. Very few cases of recovery are on record, and as a rule it lasts as long as the patient lives. Remissions and exacerbations are frequent, the latter often being provoked by some accidental illness or some real cause of worry and anxiety outside the delusional system.

The above description is an outline of the most common form of delusional insanity. In some cases the delusional system centres round the patient's own body and the fancied disorders of its various systems. He may allege he has cancer, tubercle, syphilis or some obscure affection which cannot be diagnosed. Whatever the disease, the patient becomes absorbed in its supposed symptoms and can talk and apparently think of nothing else. Doctors, charlatans, and various "cures" are tried one after the other, but the patient remains convinced that no one understands his complaint and no one can do him any good.

In other cases, religion forms the basis of the disorder. The patient may announce himself as a prophet or the founder of a new religion, and may regard his hallucinations as evidence of divine revelation. The litigious paranoiac brings suit after suit in the courts against those who he supposes have aggrieved him: no decision of any sort ever satisfies him. The political paranoiac has firm belief in some nostrum he is convinced will set right the wrongs of some section of society. Delusions in the field of love are apt to be a most serious annoyance to the object of the patient's affection. The patient by letter-writing, presents and personal attention becomes such a pestiferous nuisance that the assistance of the police has to be invoked. In other cases, the patient erroneously believes himself or herself to be the object of some unfortunate person's love, and may seek police protection from an anticipated abduction by some one who may even be ignorant of his or her existence. Delusions of jealousy may be the most marked symptom in some cases, the object of suspicion being liable, if he bestow a casual glance on any other woman than the patient, and even if he happens to sit next to one in a church or theatre, to torrents of abuse.

Treatment.—The child of suspicious and touchy character requires

especially careful educational handling. Judicious training in the society of those of his own age and a little older, healthy competition by which he will find his level in work and play, and lessons which will teach him to unbosom himself and not to nurse his grievances, real or supposed, will all assist to form a point of view little favourable to the growth of delusions. On the other hand, it must be remembered, many a child of sensitive disposition retires into himself when exposed to the not too kind society of his school-fellows, and from that retirement may never emerge unless taken in hand by an adult who understands him. It is in such a defensive position the soil is prepared for seeds which may afterwards develop into delusions.

In the early stages of the disorder something may be done by analysis and tactful influence to neutralise the morbid bent of the patient's character, but when the delusional system has become established little avails to overthrow it. So long as the patient's behaviour is not a nuisance to society and harmful to himself, certification is not indicated, but on the smallest sign that the patient feels resentfully towards any person or body of persons whom he regards as hostile to him, it is as well to certify, seeing that the step between such resentment and retaliation is but a short one. In this, as in all mental disorders, careful attention to the physical health is of importance.

IDIOCY ; IMBECILITY ; FEEBLE-MINDEDNESS ; MORAL IMBECILITY ; DEGENERACY

Definitions.—The following definitions of idiocy, imbecility, feeble-mindedness and moral imbecility are derived from the Mental Deficiency Act, 1913. They were made for the purposes of the Act, and are convenient and as correct as any hitherto alternatively proposed.

Idiots are persons so defective in mind from birth or from an early age as to be unable to guard themselves against common physical dangers.

In imbeciles, the mental defect, existing from birth or from an early age, does not amount to idiocy, but renders them incapable of managing themselves or their affairs, or of being taught to do so.

Feeble-minded persons are those whose mental defect has existed from birth or from an early age, but does not amount to imbecility, yet is so pronounced as to require care, supervision and control for their own protection or that of others, or, in the case of children, are those who appear to be permanently incapable of receiving proper benefit from instruction in ordinary schools.

Moral imbeciles are those who from an early age display some permanent mental defect, coupled with strong vicious or criminal propensities, and on whom punishment has had little or no deterrent effect.

The Mental Deficiency Act, 1927, more closely defines "mental defectiveness" as a condition of arrested or incomplete development of mind existing before the age of eighteen years, whether arising from inherent causes, or induced by disease or injury.

The classification of the first three states obviously merely consists in a useful grading of mental capacity, persons presenting a total or an almost

total absence of intelligence being called idiots; those with rudimentary intelligence, imbeciles, and those with yet a larger amount of intelligence, feeble-minded.

Ætiology.—The causes of mental defect may be conveniently divided into those operating before, at the time of, and after birth.

A family history of mental or nervous disease and especially of epilepsy is very common. Consanguinity of the parents has been supposed to be a cause, and it might be as well, with a view to the elucidation of the supposition, that a study of the products of incestuous unions should be systematically undertaken.

Alcohol and other intoxicating agents, operating in either parent or in both, before or at the time of conception; infections, especially syphilis, in either parent at the time of conception or in the mother during gestation; and emotional shock, worry, accident, physical disease or alcoholism of the mother while pregnant, are all alleged causes. The Wassermann reaction is so frequently found to be positive in the mentally defective, that it seems probable syphilis plays an even more important part than has hitherto been suspected.

At the time of birth, prolonged labour, and other anomalies of parturition, and the use of forceps appear in some cases to have had a disastrous effect upon the cerebral cortex of the child.

After the birth of the child, infections or accidents associated with convulsions, meningitis and encephalitis seem to arrest a development which until then had proceeded normally. The hydrocephalic variety occurs as the result of imperfect circulation of the cerebro-spinal fluid, whereby it is collected and dammed up in the ventricles of the brain or upon its surface within the meninges, and by its pressure interferes with proper development. This imperfection of circulation is due to closure of the foramina between the various spaces containing the fluid, in some cases brought about by inflammation and in others by congenital defect. In the case of endemic cretinism climate, soil, character of the water supply, bad hygienic surroundings, heredity and consanguinity have been assigned as causes. There is no doubt, since the improvement of sanitary conditions in some of the districts in which cretinism has been endemic, that the incidence of the disease has been less. In sporadic cases, alcoholism, syphilis, tuberculosis in the parents and infections of the mother during pregnancy are alleged causes. It has been conjectured that in some cases a thyroiditis has occurred during an infection and this has resulted in subsequent atrophy of the gland.

In the Mongolian type of idiocy, syphilis and tuberculosis in the parents, and emotional shocks, frights, worries and ill-health occurring to the pregnant mother have been presumed as causes. This type appears accidentally in a family in whom there is no history of nervous or mental disorder. The affected children are often among the younger members of large families, the mothers being somewhat advanced in life. Hence uterine exhaustion has been proposed as a cause.

Pathology.—The shape of the skull varies. It may be acrocephalic, platycephalic, plagiocephalic, scaphocephalic, macrocephalic or microcephalic, the last form being the commonest. In some cases the sutures ossify prematurely, and in others either later than normal, or never. Except in hydrocephalus and in a few rare instances in which the brain is larger and heavier

than normal (*hypertrophic sclerosis*), its size and weight are diminished. The hemispheres are sometimes unequal in size, one being atrophied. In a few cases, an important part of the brain, as, for example, the corpus callosum or the central masses of grey matter, is absent. There may be hydrocephalus or porencephalus, that is, a cystic degeneration of the cortex, or scattered nodules of sclerotic tissue, of the size of filberts; or certain of the gyri may be small or absent and the sulci between them wide and deep. The grey matter may be unduly hard or unduly soft, and there may be signs of a past meningitis or encephalitis. Histologically, the nervous tissue cells are reduced in quantity and degenerate in quality, while the fibrous tissue elements are increased.

In amaurotic family idiocy the anatomical changes are those of a primary degeneration of the cell bodies of the cortex, the most completely affected parts being the interfibrillar protoplasm.

In cretinism, ossification of the sutures of the skull is late and the bone is thicker than normal. The dura mater also may be thickened and more than usually adherent. The volume and weight of the brain are diminished and the cortex, corpora striata, cerebellum and medulla but ill-developed. In many endemic cases the thyroid is enlarged, with a superabundance of connective tissue, or cystic degeneration may be present. In other endemic cases and, as a rule, in those that are sporadic, the thyroid is atrophied and its glandular elements replaced by fibrous tissue, with a general proliferation of fine subcutaneous connective tissue: the walls of the blood vessels are thickened.

In the Mongolian type the cerebral cortex is quantitatively diminished and its structure is less complex than normal. The cortical cells are less thickly set. The sulci are not so numerous. The cerebellum, medulla and cord are likewise diminished in size.

Symptoms.—The most profoundly affected idiots are mindless. Their special senses, when present—for they are often defective or absent—convey impulses which are not transformed into perceptions: in other words, there is no mind to refer sensations to external objects. No judgments, even of the most elementary sort, are formed. There is no liking, disliking, memory or desire. The instincts of the brute are absent. Patients such as these are incapable of sitting up or walking, and taking food resolves itself into a reflex act which occurs when a foreign body stimulates the mucous membrane of the tongue and pharynx. They are completely incontinent; often congenitally deformed, rickety or suffering from hemiplegia, diplegia or paraplegia. Rumination, athetoid movements and meaningless noises form their only modes of activity. The face is expressionless or foolish-looking, the lips not properly opposed and saliva dribbles from the mouth. Strabismus, cleft palate, hare-lip and anomalies of trunk, limbs and genitals are frequent. Such patients do not develop and die early. In rather less extreme cases, patients after a time recognise their attendants and dislike to be absent from them. They may, perhaps, be taught to control the bladder and the rectum and to feed themselves. They may have preferences as to their food, and even be able to say a few words or sentences. Beyond these few likes and activities, there is no evidence of mental function. In some patients, sexual instincts are early developed, and they will masturbate, display their genital organs in public, and run after members of the opposite sex quite shamelessly. The temper is often easily roused and conduct may

be violent. Many are epileptic. In a few cases, amidst a desert of mental sterility, some one faculty, as for music, or arithmetic, or memory, is found to be abnormally well developed.

The addition of various faculties and improvement in their quality may result in the higher grades of imbecility and feeble-mindedness and it is unnecessary here to describe these in detail. Some imbeciles have sufficient faculties to enable them to be converted by education into harmless and happy members of institutions for their like, or even of their own families, while the feeble-minded may be taught some simple occupation and so may become not wholly economically useless to the community.

Intelligence tests have been devised for the purpose of comparing the mental state of defective children with a standard of attainment ascertained by experience to be approximately correct for the normal child. Essentially the tests consist in attempts to measure the powers of perception of the defective child, his capacity to assimilate the rudiments of scholastic education, to perform actions more or less complicated, to solve very simple problems and to develop elementary abstract ideas. Sets of questions and problems are arranged in order of increasing difficulty, the most easy being those which should be answerable by the normal child of three or four. If the child cannot answer the set of questions proper to his age, but can only deal with those proper for a younger child, he is set down as being of a mental age by so much less than his real age. His development is at any rate regarded as delayed.

MONGOL TYPE

In this type the palpebral aperture is narrow and almond-shaped and its long axis is directed downwards and inwards, while at its internal corner the epicanthic fold of skin concealing the caruncle is evident. The nose is snub with the root flattened out, the malar eminences are advanced and the skin over them red. The oral aperture is small, but the lips large. The tongue is large and rugose and tends to protrude. The upper parts of the ears overhang the lower. The head is small and round and the sutures often remain patent. The arch of the palate is high and narrow, with a median groove. The teeth are usually carious and may be placed abnormally. The signs of rickets are often present. The abdomen is pendulous and protuberant. The hands and feet are short, broad and thick, the fingers taper and the little finger is often radially deflected. Ligaments around joints are slack. The genitals and mammae are small. Congenital cardiac lesions are common. The degree of mental deficiency is profound, though the patients tend to show a little more affection than do other types, and are less irritable. Development is very slow and death usually occurs early, often from tuberculosis.

CRETIN TYPE

The arrest of development occurring in this type is probably due, for the most part, to thyroid insufficiency. This gland is occasionally enlarged, but in most cases atrophied. The mental condition varies and there is more or less idiocy, imbecility or feeble-mindedness. The head is generally large, especially in the occipital region. The face is podgy in appearance, the root of the nose being flattened, the eyelids puffy and obscuring the eyes, the lips thick and open and dribbling is common. The tongue is large and the teeth

carious and ill-placed. The neck is short and stubby, and the supra-clavicular fossæ are filled in or converted into protuberances. The abdomen is large. The legs are curved as in rickets, and the hands and feet large and splayed. The skin and hair are dry and harsh, and the latter is scanty. Everywhere there is an œdematous appearance, the feeling imparted to the finger on pressure suggesting, however, elasticity rather than the dough-like yielding resistance of œdema. The extremities are purple in colour and cold to the touch. The genitals are small. The respiration and pulse rates are slow.

For the treatment of Cretinism, see p. 469.

AMAUROTIC FAMILY IDIOCY (see p. 1478).

EPILOIA

Under this term are included cases in which feeble-mindedness and epileptic fits occur in association with adenoma sebaceum, fibrous nodules of the skin, nodular sclerosis of the brain, and renal tumours.

MICROCEPHALIC TYPE

The small size of the head is the outstanding feature. The face is like that of a monkey, and the ears are large and protrude laterally.

HYDROCEPHALIC TYPE

The head is large and may be gigantic, the face remaining about the normal size. Patients may be of very good and indeed of normal mental development, but, in most instances, are defective. As a rule, some elementary moral and social notions are present, but the will-power of patients is feeble and they are often absurdly vain. They are not long-lived.

Mental defect is frequently associated with the hemiplegia, diplegia and paraplegia of infancy. Its grade varies widely and depends on the amount of damage the cortex cerebri has sustained.

Treatment.—Treatment consists in patient and systematic endeavour to make the most of such mental power as may be present. Patients are roughly divided into the educable and the ineducable, but it is undesirable to class them until some educative effort has been made by properly qualified persons. Even the seemingly most unpromising cases may in some instances have elementary notions of the control of the sphincters instilled into them. Others can be brought into some sort of rudimentary relation with the external world by laboriously teaching them such physical qualities as weight, roughness and smoothness, hardness and softness, colour and shape. They may be taught to learn the feel of the ground by their feet, of the upright position and of motion. Some may be made eventually to stand upright and even to walk. Similarly the hands may be educated so that the patient may feed himself, dress and undress, wash, use such simple tools as a broom or scrubbing brush or, in the higher grades, exercise some handiwork such as laundry work, basket- or shoe-making. It is seldom in the home circle that skill and time can be found for the conduct of such education, and patients have far better chances in special schools or institutions. The somatic health requires careful attention, and mental progress will largely be proportionate to the physical standard that can be attained.

MORAL IMBECILITY

Symptoms.—Among the insane, improper and criminal conduct is frequent. It may be due to impulsiveness; that is, as it is customary to explain the matter, to the operation of automatic centres acting independently of, and indeed perhaps in opposition to, the highest centres subserving judgment and will. In the automatism of epilepsy we have the most striking examples of the achievement of complicated actions, even over considerable periods of time, in the seeming absence of the patient's usual personality. In such a state crime of a complicated sort may be committed. In psychasthenia and other disorders, obsessive or imperative ideas which force themselves into the field of the attention and usurp it, may issue in action, perhaps of a criminal character. The systematised delusions which occur most pronouncedly in chronic delusional insanity and to a less extent in confusional insanity and dementia præcox, may, for example, prompt the patient to rid himself of his supposed enemies by homicide. The delusion of the melancholic that his family is hopelessly ruined, may lead him to murder its members to save them from the miseries of destitution and starvation. A sexual pervert may commit crimes in satisfaction of his abnormal tastes. An imbecile or feeble-minded person may commit an act, say, of incendiarism, without having sufficient sense to appreciate its consequences, or the person in a state of acute confusional insanity may perpetrate a crime because he is at the time too muddle-headed to know what he is doing or why he is doing it.

The moral imbecile knows what he is doing and the consequences of his acts, and he does not suffer from impulsiveness, obsessions, perversions or delusions. His moral sense is lacking and he has no appreciation of right and wrong. The condition dates from infancy and becomes more obvious as the looked-for results of education fail to appear. As a child an extraordinary indifference to the feelings of others is noticeable. This is not only due to the self-absorption, thoughtlessness and ignorance which in the case of the ordinary child make him neglectful of others, but, in addition, must be attributed to a defect of feeling, displayed not only to strangers, but even to the nearest members of the patient's own family. He is disobedient to those in authority, untruthful, jealous, bad-tempered and cruel in his dealings with other children or with animals. Later, when educational efforts are made, he will probably be found to be idle, though quite possibly equal to the average, or surpassing it in intellectual capacity. Later still, gambling, thieving, drinking and sexual licence become added to the catalogue of the patient's vices. Every patient does not necessarily exhibit the entirety of such moral imbecility. In some, the moral lacunæ are confined to one or two virtues, such, for instance, as sobriety and honesty. Some spend their lives amidst general approbation until it is discovered they cannot keep their hands from picking and stealing, at any rate in shops; while others become affluent on business transactions involving widespread ruin and misery, to the effects of which they are utterly indifferent.

The deterrent effects of punishment are scarcely operative, and its pains only serve to sharpen the wits of the patient to enable him to escape it in the future. Educational measures are almost equally useless. If the delinquencies be not such as are illegal, or in the event of their being criminous

if the patient has been sufficiently astute to escape the consequences, he will at any rate almost certainly be the terror and scourge of his family.

Treatment.—The treatment of such persons consists in their removal to surroundings where their activities are restrained and the consequences of their actions are reduced to a minimum of bad effect. Psychotherapy by analysis or re-education should be attempted.

THE DEGENERATE, UNBALANCED AND ECCENTRIC: AKATASTASIA

Ætiology.—Persons coming under these headings may be regarded as displaying some evidence of the failure of the vital force, transmitted to them by their forbears, to produce an average quality, either somatic or mental. The symptoms are not found to be impartially distributed among all the members of a family; their incidence is frequently concentrated upon certain individuals. Why this should be so, if the initial defect lies only in the quality of the transmitted material or force, it is difficult to determine and it may well be the subtle influences of a defective environment have something to do with the production or accentuation of symptoms. Careful examination of early life often discloses a history of most unsatisfactory home conditions during infancy and childhood; while analysis may show that mental evolution has proceeded along abnormal lines.

Symptoms.—Patients are frequently particularly intelligent, and occasionally brilliant, but there is a lack of balance between the various faculties, one of which is probably not efficiently kept in order by the others. Imagination may be untrammelled and without judgment, or in other and more rare instances judgment proceeds with leaden feet unassisted by a suspicion of imagination. Memory may be exceptionally good, but owing to want of judgment may merely introduce unutilisable additions to the data of present problems. Capacity in childhood is often precocious and particular faculties, such, for instance, as for arithmetic and music, are remarkably developed, but their fruitful application is thwarted by want of attention, caprice or obstinacy. At the time of puberty, vague and often absurd aspirations after distinction, affectedness, religiosity and sexuality are common features. Grown up, such patients, if not wholly idle, frequently occupy themselves in a dilettante fashion with the Arts—poetry, literature, painting and sculpture. Rarely producing anything of value, they tend to affect extremes of fashion; are anti this, that or the other; doubt and deny, on quite inadequate grounds, current beliefs and modes of thought; see short ways to the improvement of every one and every thing; are Utopians, and, above all, set a high value on themselves. Their defects lie in want of breadth of view, of a sense of due proportion and, frequently, of common morality; while such details of business as paying bills, punctuality and keeping of engagements are almost beneath their contempt. The result of these defects, which unfortunately outweighs the value of the product of the patients' cleverness or manipulative skill, renders them of small use in the professions, or in looking after the affairs of others or even their own. Affectivity is often small in quantity and poor in quality; with much display of emotion there is but little depth of affection or sympathy. Periods of feverish activity alternate with periods of complete idleness. Affectations in hair-dressing, clothes, jewellery, in ways of talking and walking; eccentricities

shown in excessive love for flowers, animals, furniture or dress ; extravagance or miserliness ; preferences for the absurd in love, religion and the Arts ; gambling and drunkenness, may all be symptoms of degeneration. Hypochondriasis, cynicism, misanthropy and ill-placed or ill-guided philanthropy are still more pronounced and noticeable symptoms. Sexual perversion, inversion and other such anomalies are not uncommon.

Patients may exhibit some or many of the above-mentioned symptoms, without possessing that specious show of cleverness and brilliance which often induces the world at large to mistake the degenerate for a genius. They are mentally slow, their instruction is laborious, and at school they are behind the standard usually attained by those of their own age, though they may display that eminence in one faculty which is not infrequent even among the imbecile. Eccentricities, affectations and mannerisms may be marked, while judgment and will-power are weak. From such a mental make-up it is obvious the symptoms of more marked disorder may easily emerge, and in fact the approximation to dementia præcox and paranoia is sometimes very close. Indeed, in some cases the patient commencing as a degenerate passes eventually into the category of dementia præcox. The degenerate is an incomplete example of dementia præcox, while conversely dementia præcox is a term of the process of degeneration. Degenerates are also prone to confusional insanity, mania and melancholia. The last is likely to be of the delusional variety with ideas of culpability, hypochondriasis and persecution. Patients commence by misinterpreting the words and behaviour of those about them, seeing in them references to themselves ; or they read meanings into newspapers and advertisements which, they allege, imply they are being insulted or attacked, or are great personages, or are being communicated with by some one in love with them. They may develop some social or political scheme and support a thesis in its favour with extraordinary persistence and energy. Political assassins, who think that by the removal of some prominent person the system of government of their countries will be altered and perfected, often come of this class. Or having, perhaps, had some small difference over business affairs or having suffered some slight reprimand at the hands of an official superior, the degenerate exaggerates the injury and elaborates wholly disproportionate efforts to get himself set right.

Similarly, some losing cases at law will not be content with the decision, but repeatedly appeal to higher courts and spend all their time, energy and substance in the useless prosecution of an idle cause. Eventually, they impeach the integrity of their own advisers and of the judges before whom they have appeared, and perhaps proceed to secure what they regard as justice by assault and homicide. Sometimes the degenerate will be given to the invention of articles which are of no use to any one, and will allege that the failure of his absurdities is due to the jealousy or fraud of others. The religious degenerate may invent ecclesiastical systems, or improve upon older religions by blending with them his own crude notions. Some degenerates exhibit the acutest jealousy and see in every act of the unfortunate victim a proof of his infidelity towards themselves, while others seeing the tokens of love towards them in the behaviour of a selected individual harass him, perhaps for years, with evidences of their own affection.

Impulsiveness is common : it is irresistible, and the patient is fully conscious of what he is doing when it issues in action. The impulse may

be for taking certain poisons, for instance, alcohol and morphine, or theft, murder, suicide, incendiarism or sexual crimes.

The following is a brief catalogue of some of the more important physical abnormalities known as the stigmata of degeneration. So far as general conformation is concerned gigantism, infantilism, feminine appearances in the male and masculine in the female are noteworthy. The head may be too large or too small; asymmetrical, flat-topped or pointed at the vertex; too round, too oval, too narrow or too broad. The face may be asymmetrical. The orbital cavities may be too near to each other or too far apart. The palpebral aperture may show odd shapes, be too round or too oval or too large or too small. There may be anomalies in colour and structure of the eye itself. The ears may be abnormally set upon the head and their shape peculiar. The nose similarly may be too large or too small, bifid or imperforate. The mouth may be too large or too small, with hare-lip or cleft palate. The palate may be unduly arched or pointed. The teeth may appear late and the first dentition may persist. Teeth of either dentition may decay early and be badly set or too few or too many. The tongue may be large, small or bifid. The jaws may be too large or too small. The shape of the trunk may be anomalous. The spine may show various deformities and may be bifid. Anomalies of situation and in the development of the thoracic and abdominal viscera and hernial protrusions may be found. Large, small and coalesced fingers and toes may occur, and whole limbs may be unequal in size to their fellows. The genitals may be unduly large or small. Testicles may be undescended or absent. Epispadias, hypospadias, hermaphroditism, atresia of the vulva, large or small labia or clitoris may be present. Albinism, vitiligo, anomalies in the thickness and colour of the skin and the set and colour of the hair may exist.

INSANITIES OF INVOLUTION

Under this title will be included the mental disorders associated with senility, premature senility, arterio-sclerosis, cerebral hæmorrhage and thrombosis.

SENILITY

The mental symptoms of senility are analogous to the physical in that they betray enfeeblement of faculty.

Ætiology.—The physical alterations and the functional disabilities of senility are due to wearing out of the tissues, the process being accelerated by the vast variety of intoxications brought to bear upon the body throughout life. Alcohol, lead, tobacco, syphilis and other infective disorders, gout, constipation or gastro-intestinal intoxication without constipation, may separately or in combination play a part. It is at present doubtful if physical or mental overwork and worry directly exhaust the tissues or whether they imply a katabolic process during which toxins are formed.

Pathology.—Macroscopically, thickening of the meninges, dilatation of the cavities of the brain and atrophy of both cerebrum and cerebellum are to be found. The vessels may be manifestly degenerate, and small hæmorrhages

and patches of sclerosis may be seen. Microscopically, atrophy and disappearance of the cortical cells, diminution of the number of the fibres and proliferation of the neuroglia are noticeable.

Symptoms.—The mental symptoms of senility are of two kinds, those arising from loss of power and those due to the perversion of such faculties as remain. It is possible that this last results from the activities of centres not the highest which in the presence of the decay of the latter are unrestrained. Weakening of power is distributed generally, though in some cases there seems to be a special incidence upon some one faculty. The power of perception diminishes and observation becomes less acute. Attention is concentrated and held with difficulty, so that the power of fixing recent events in memory becomes poor. The affections, of which the sentiments of love, hatred, hope and fear are examples, become enfeebled, and losses of friends, fortune and health produce an effect which often seems surprisingly small. Besides weakening of the power of fixation in memory, there is also diminution of that of conservation. The loss of memory of events progresses, as it were, into the past. Events of comparatively a short time since are forgotten, while the memory of events long past is preserved. In the end, the writing on the tablets of the memory is wholly erased and nothing at all is remembered. Judgment becomes hesitating and uncertain. Appetency fades and the desires of the senile are but of small range. The power of the will is reduced and decision becomes difficult. Manners are often disregarded and even the sense of ordinary decency may be obliterated.

All forms of mental symptoms may occur on this basis of decay, such as mania or melancholia, perhaps with delusions of unworthiness, ruin, or perhaps of the anxious type, occurring in isolated or intermittent attacks or alternating. There may be confusional insanity with or without hallucinations, auditory hallucinations being particularly frequent among the deaf, and associated with temporary delusions of hypochondriasis, grandeur, jealousy and erotism. In this state the patient may make attempts at indecent assault or at rape, or other forms of violence, or at suicide. The delusions may sometimes be fixed and systematised and the resemblance to delusional insanity very great. In certain cases patients become childish and renew infantile tastes, as, for instance, that for playing with toys and dolls.

Superadded to the dementia, *presbyophrenia* or *involutional schizophrenia* may occur. In this case there is confusion, amnesia, loquacity and fabulation, the whole frequently tinged with euphoria. It may occur as a result of even slight infections or auto-intoxications, and passing away leave the patient at a lower level of mental power than he occupied before.

A syndrome, resembling Korsakoff's polyneuritic psychosis, combining general peripheral neuritis with loss of memory, pseudo-reminiscence and preservation of a large measure of judgment and decency of conduct, is sometimes seen.

In the absence of any particular disorder, the uncomplicated physical symptoms of senility are weakness, liability to fatigue on but a small amount of exertion, giddiness and either insomnia or undue sleepiness. The patient gradually gets thinner and loses appetite.

Course.—Senility may come on very gradually over a long period of years or its changes may follow upon each other with almost startling

rapidity. Death eventually comes from cardiac, cerebral or respiratory complications or from intercurrent disease.

Treatment.—The treatment consists in adapting the activities of the patient to his powers, which, it must be remembered, are constantly lessening. Food, work and recreation have to become simpler in character. It is useless to goad the tired body to do things for which it is no longer able. If mental symptoms of a pronounced character arise, it is better and kinder to keep the patient at home in all cases where proper provision can be made for looking after him. It is particularly necessary to exercise close supervision in those cases in which the patient is likely to indulge in erotic conduct or to attempt assaults or suicide. The exercise of undue influence by attendants, friends and relations in order that they may become beneficiaries under the patient's will should, so far as possible, be guarded against, and the medical man may properly warn those concerned of the increased suggestibility and diminished will-power of the patient.

ARTERIAL DISEASE

Arterial disease plays a large and perhaps preponderating part in the production of the symptoms enumerated under the head of Senility, but, as is well known, it may commence at a period of life which in length of years cannot be called one of senility.

Symptoms.—The symptoms of arterial disease, so far as the nervous system is concerned, may come on very insidiously, quite rapidly or even suddenly. Loss of energy, fatigue following upon slight exertion, diminution of the power of attention, headache and giddiness are very common early symptoms. Some change in character such as irritability, lessening of business faculty and instability of the emotions may have been noticed. Sleep at night is poor, while during the day the patient may scarcely be able to keep awake. With intellectual enfeeblement, there may also be such symptoms as absurd euphoria, indifference to those interests which have hitherto been most cherished, confusion, stupor, anxiety, agitation, hallucinations and delusions. The physical signs of senility with vascular sclerosis, myocardial degeneration and renal sclerosis are also frequently present, as well as such effects of vascular degeneration as pareses, aphasia and paralysis, sometimes transitory and sometimes permanent.

CEREBRAL VASCULAR LESIONS

The symptoms produced by hæmorrhage and thrombosis of cerebral vessels are in most cases symptoms of involution in so far as they are the results of degeneration of vessels. Thrombosis, embolism and hæmorrhage may in a few cases be the result of trauma, septic or other infection or anæmia, and here involution cannot play any part. Such cases are, however, for convenience included here since the symptoms are similar to those obtaining in hæmorrhage and thrombosis due to vascular degeneration.

Symptoms.—Before the occurrence of the stroke, changes in character and affectivity may have been noticed, together with enfeeblement of memory and impairment of the sense of morality and decency. Inattention, fussiness

and apprehensiveness may have become accentuated. Such symptoms are those of arterial degeneration and, perhaps having previously escaped comment, are only brought to light when the patient's history is being elicited after the stroke has occurred. The initial mental symptoms following the stroke are those of confusion, accentuated and complicated by failure to recognise and classify sensations carried by intact sense organs (agnosia), and inability to execute acts even though the motor apparatus, from the upper motor neurons downwards, is intact (apraxia). A normal relationship with the outside world may never be regained, and confusion of varying degree may persist for the rest of the patient's life. There may, in addition, be states of excitement and depression, with delusions of grandeur, ruin, persecution or concerning religion or love. Hallucinations of all sorts, but especially of hearing and sight, may occur. The patient is likely to be impulsive, and his conduct in general may, in obscenity or in other ways, be different from what was usual with him in health.

Treatment.—The treatment of the symptoms of vascular degeneration is essentially the same when of the nervous as of any other system. The impulsive, absurd and improper behaviour which is the symptom of the mental disorder, requires attentive watching, and if this can be secured at home there is no reason why the patient should be removed elsewhere.

PSYCHASTHENIA

Symptoms at one time frequently included in the comprehensive syndrome which has gone by the name of neurasthenia have been separated from it and have come to be regarded as constituting a clinical entity which has received the name of psychasthenia. It has lately been sought to divide psychasthenia in its turn into an obsessional state and an anxiety state, but both for convenience of description and because this division is not everywhere accepted, the term psychasthenia has been here preserved. The chief points that appear to remove the symptoms which are termed psychasthenic from the syndrome known as neurasthenia are : (1) that there is an absence of such obvious exciting causes as circumstances that exhaust, or toxæmia ; (2) that the symptoms are not amenable to treatment appropriate for nerve exhaustion, though they may be temporarily ameliorated thereby ; (3) that good somatic health often exists alongside psychic symptoms, though the latter may be accentuated during somatic ill-health ; and (4) that there is much more frequently a history of mental and nervous disorders in forbears. The terms neurosis, psycho-neurosis and psychosis have been avoided in this section inasmuch as they convey different notions to different persons and, indeed, are used with varying meaning by many individual authorities.

Ætiology.—Many patients suffering from psychasthenia are derived from families of bad nervous and mental history, but not all the members of such families are necessarily affected. Whether the inherited defect or the home atmosphere made by neurotic parents, in which the patients' earliest years are passed, is the more inimical to balanced growth, remains a moot point, but it is at least noteworthy that psychasthenic patients frequently proceed from homes which for some reason have not been happy in that

one or other parent has been a constant source of irritation or resentment ; or the child has been imbued with ridiculous fears—for instance, of the dark or of catching cold ; or the parents have bickered or quarrelled ; or parents or other attendants have suppressed too ruthlessly infantile longings or affections, or have teased or bullied ; or, on the other hand, have encouraged unhealthy sentimentalism ; or because something really catastrophic has occurred—for instance, a fire, an accident, an assault, or the death of some one much loved ; or, lastly, because the child has never been taught a due amount of consideration for others, unselfishness and self-control—in short, has been spoilt.

The trend of more recent psychological work has been vastly to extend the meaning of education and to include in it not only formal education but also all the influences of example, speech and environment dating from earliest infancy. The acquisitions of mental life are not all represented in consciousness ; many associated with emotional tone and with action have by repetition become automatic ; and others, owing to their incompatibility with notions later developed, have become repressed and in the normal individual do not so obtrude themselves that conscious thought and conduct are affected. In abnormal individuals, however, these latent or repressed acquisitions tend to affect conscious thought and conduct and so to produce symptoms.

The unstable character with which many, if not all, psychasthenic patients appear to be endowed from an early age may be upset by circumstances often of a very trifling character ; small disappointments or disagreements, social or professional slights and trivial somatic disorders or fatigue may produce unpleasant psychic effects of quite extraordinary character, intensity and duration.

Symptoms.—Psychasthenia comprises obsessions, impulses, imperative ideas, doubts, scruples, infirmity of will or abulia, morbid fear or phobia associated with particular circumstances, and states of generalised panic, fear and anxiety. Differentiation between obsessions, impulses and imperative ideas is practically difficult. Imperative ideas are such as insistently intrude themselves into consciousness without reference to the trend of thought proper to the patient in the circumstances in which he finds himself ; for instance, an idea may insistently crop up in a patient's mind that he should break with his stick the electric light bulbs in a building in which he may find himself. He does not wish for any conscious purpose whatsoever to break the bulbs, the idea is in no way consciously associated with the purpose for which he is in the building and he is aware that the breaking of the bulbs will afford him no satisfaction, nevertheless he cannot put aside the idea. Imperative ideas may be, as might be supposed, of infinite variety.

An obsession may be defined, though it is not always, as an imperative idea which issues in action ; for instance, the patient may not only feel himself compelled to think of breaking the bulbs, but may feel himself compelled to take action and actually to break them. As imperative ideas are varied, so also are obsessions, and may consist in some triviality, such as touching certain objects, or in such grave actions as taking others' goods, or in assaults, even of a homicidal character.

A morbid impulse may be defined as an action without previous conscious ideation or with ideation of extremely short duration ; for instance, the

patient smashes the bulbs directly the idea comes into his mind or, indeed, without the idea being formulated in consciousness.

Of the nature of negative obsessions are the symptoms of morbid doubts, scruples and infirmity of will. In such states thought and action are hesitating, since to every idea proposing a line of thought or of action there is at once opposed an idea of negation; for instance, the matter to be decided is whether the patient shall go out-of-doors or stay in, and whether the occasion be trivial or important, an argumentative process commences and proceeds in the patient's mind until very possibly the opportunity for going out is lost. Scruples similarly arise when either trifling or momentous issues are involved.

Imperative ideas, obsessions, impulses, doubts, scruples and weakness of will are almost always accompanied by an affective or emotional tone of unpleasantness, the emotions frequently being concerned with objects normally of indifference or of no value to the individual. Such may consist of mere annoyance at the unwished-for cropping up of foolish, unseasonable and useless thoughts; or apprehension that the condition is one which will pass into insanity; or disgust at the possession of an uncontrolled, puerile and feeble character; or, lastly, a state of fear, insecurity and anxiety which is seemingly wholly unaccountable and which cannot in reason be based on the realities of the situation in which the patient finds himself. Many of these fears have received names, the commoner being *Agoraphobia*, the fear of open spaces; *Claustrophobia*, the fear of being shut in—for instance, in a railway carriage or in a church; *Nosophobia*, the fear of catching disease; and *Erythrophobia*, the fear of blushing. In some persons morbid panic and anxiety are not consciously associated with any particular set of circumstances in which the patient may find himself and may occur either as a continued state of fearful apprehension or in paroxysms.

Symptoms of uncontrollable apprehension and anxiety, whether they take the form of unaccountable fears of the present and the future, or are particularly associated with such disordered functions of the cardio-vascular, respiratory, gastro-intestinal or other systems, as rapid or intermittent heart-beat, dyspnoea, indigestion, epigastric discomfort or "neuralgia," or nocturnal terror, have been grouped under the head of *anxiety neuroses*. Attention has been particularly focused upon these symptoms by Freud's theory that they result from some deviation from "normal sexual life," and by the large crop produced by the Great War.

To differentiate these various symptoms from somewhat similar ones occurring in other abnormal mental states, it should be remembered that there is no marked disorder of perception or of judgment, of memory, of the sense of relationship to time and space or of the sense of personal identity. The patient recognises the morbid character of his affection and the absurdity of his doubts, questionings and foolish conduct. In certain cases, however, in which the imperative ideas are of a harassing and worrying character, or in which the obsessional or impulsive acts are wearying, it may eventually happen that upon the psychasthenic state are engrafted the symptoms of exhaustion or confusional insanity or of melancholia.

The course of the symptoms of the psychasthenic state is extraordinarily variable. Some persons present such symptoms throughout life, the symptoms varying in intensity with somatic health and with mental equanimity, and

perhaps scarcely at all interfering with the course of business or pleasure. Both the patient and his friends learn to bear with his mild eccentricities and, indeed, successfully to ignore them. Others suffer from occasional attacks which appear to be entirely episodic, which leave the patient apparently perfectly well between them and which eventually cease to recur. Others again, from the severity of their symptoms, or, as indicated above, from their complication with other mental disorders, break down completely and remain invalids for long periods or for the rest of their lives. No psychasthenic should be considered as finally rid of his affection until his death, and this, indeed, no matter what the nature of the methods of treatment to which he has submitted.

Treatment.—The education of the child derived from families the members of which suffer from nervous or mental affections should be particularly carefully conducted from the earliest infancy. Affection for parents, nurses and others in the child's immediate neighbourhood should be duly balanced, and the affection shown to him should be displayed rather in a cultivated care for his present needs and his future development than in the coddling and caressing which not infrequently alternate with impatience, petulant scolding, shaking and slapping. The ideal of home life which has for long been the aim of almost all the most civilised human communities has perhaps in part consciously or unconsciously been formed by experience of the unhappy effects upon children of early life in which the relations between parents and others has not been harmonious. It is at any rate noteworthy that many nervous and mental patients come from families in which there has been a very decided want of harmony. It is not possible here to do more than to emphasise the importance of a well-thought-out system of education in the case of predisposed individuals and to point out the disastrous effects of a haphazard upbringing by those who themselves are sufferers. In an established case of psychasthenia it is as well to inquire into the circumstances of the education, especially the early education, of the patient; and by education is here meant not that only which is formal and scholastic but also that which lays the foundations of primitive likes and dislikes and the ideas which are associated with these affections. This inquiry may be conducted not only by the ordinary method of minutely questioning the patient but by examination of his free-associations, time-reactions and dreams. The mental enlightenment which ensues upon such an inquiry may of itself suffice to ameliorate symptoms or at any rate to afford the physician an opportunity of effecting some readjustment of the patient's ideas and affections by a process of re-education.

On the somatic side the condition of the alimentary, cardio-vascular, respiratory and renal systems should be examined and any defect remedied as far as possible. Watch should always be kept on the patient's weight and upon the amount and character of his sleep. Both should be a little in excess of the strictly sufficient. If sleep is not good, hypnotics, strictly under medical supervision, may be employed, but should be varied in character and amount. The physician must never forget that from the ranks of the psychasthenic are derived those who in taking drugs pass beyond therapeutic limits and continue their use for the pleasurable effects. Small doses of the bromides—about grs. v, t.d.s.—are often useful in allaying the acuity of anxiety and restlessness.

PSYCHOTHERAPY

Included in psychotherapy are the endeavours made by the healthy mind to influence therapeutically the unhealthy mind and through it such somatic symptoms as may reasonably be attributed to its faulty operations. The therapeutic action of material things, for instance, drugs and climate, upon the mind is not usually comprehended in the notion of psychotherapy; it may be entitled the physiotherapy of mental disorder, and will not be further alluded to in this chapter.

It is axiomatic that before the commencement of the procedures of psychotherapy a thorough examination of the body should be made, and that such derangements as may have been discovered and are amenable to physiotherapy should be treated, or at least that they should be treated concurrently with the psychotherapeutic measures. It is in cases of purely psychic origin that psychotherapy is at its best, though it is not without its uses where somatic symptoms are associated with those that are mental. If it is of supreme importance that a thorough physical examination should be made before treatment is commenced; so is it equally important that a thorough psychic examination should also be effected. Whereas, however, an adequate physical examination may be made in a few hours, a psychic examination is not unlikely to occupy a quite unlimited amount of time.

In the case of such mental affections as mania, melancholia, dementia præcox and paranoia, of which the ætiology is obscure and in which it may be supposed that there are psychic causative factors, an analysis of the mental state is very desirable, but because of the divertibility, the inaccessibility or delusions of the patient, is extraordinarily difficult save in very mild cases or during remissions.

In hysteria, psychasthenia and in certain cases of epilepsy in which the patient preserves an insight into his mental state, realises that he is in a morbid condition and desires relief, analysis is less difficult and at least can be attempted. The procedures of analysis are designed to explore those regions of the patient's mental field which are not present to his consciousness and some of which can only be discovered by special methods. Here, as it is alleged, lie concealed the sources of those processes which eventually result in symptoms.

The development of the mind in the first place takes place along the channels which seem to be laid down as guides for vital energy, that is, through the instincts, but very early in life the activities of the instincts impinge upon obstacles, some natural, some due to the laws and conventions of society and some to the character of the first human beings with whom the individual has to deal, and thus progress is retarded or thwarted or turned aside or wholly stayed. Later in life habits or automatisms, good or bad, may be opposed in many ways and by influences of very varied sorts: by the desire of sensual gratification or by a revolt from the consequences of such gratification; by the desire and struggle for worldly wealth and position or by the realisation of their essential vanity; by want of faith in high ideals or by a belief in the possibility of their realisation. All these oppositions involve an idea of mental conflict and the expression in thought of the one tendency and the repression of the other. With the repression of the idea

of an action out of consciousness goes also the repression of the affective tone associated with the idea, that is, of its pleasure- or pain-giving qualities. These are often likened to a quantum of energy which must pass in some direction or other or must remain stored up. If the affect cannot pass in the direction of the action equivalent to the repressed idea it may pass in abnormal directions and emerge as symptoms such as phobias or other unreasonable dislikes or likings. Analysis seeks these repressed ideas in order that their affects may be rightly orientated.

Further, normal psychic development passes from the primordial intensely egoistic stage, through affection for those who are near and useful in the gratification of early physical wants to an elevation which varies enormously among different persons. Some never get beyond the first stage and appear not even to care for those who minister to their comforts, others pass to the stage where affection is entirely of the order of cupboard love, and all stages of subsequent elevation may be daily observed up to the point where man transcends himself, and his ego is lost in some great ideal. At some early stage in this path progress may be checked and a morbid fixation of an affect may occur. In this case also analysis seeks the repressed ideas in order that the affect may resume its progress.

It would not be possible here to set forth in detail the procedure of analysis, and a very brief description must suffice. Dreams are examined with care, as they are regarded as a direct expression of unconscious mental processes, and the ideas presented in them are submitted to the processes of free- and time-association. In free-association the patient tells of every thought that comes into his head while the experiment is being held, regardless of its character. In the time-association test the patient is given a word and is directed to say the first word that comes into his head after he has heard it. Prolongation of the reaction interval and peculiarities in replies made are noted and compared. By these methods much of the psychic development of the patient is reconstructed and made objective, while imprisoned affects are freed.

The method of psychotherapy known as re-education would appear to involve a belief that the patient's education has been faulty, that his symptoms are due to this and are capable of being remedied by a fresh process of education. The first two of these assumptions can only be sustained if a prolonged examination of the patient's mental life is first undertaken, and can then only be held as true of the conscious part of his mentality, unless indeed the special methods of analysis are undertaken in addition. Re-education is probably in practice directed less to the enlightenment of the patient's pure cognitions, if any such exist, than to the orientation of his affections or emotions. Whatever our theories as to the fixation or abnormal deviation of affects, there can be very little doubt that neuropathic or psychopathic patients display a degree of self-interest and self-centredness which is astounding, even in this world of egoists, and for the most part the efforts of the re-educationalist are directed to getting the patient out of himself and introducing him to the possibility of other interests. Strictly speaking, conventional exhortations which are so common in medical practice may be regarded as instances of re-education. To enlighten a patient by explaining to him that pain occurring in the lower part of the left side of the thorax is due to indigestion and not to cardiac disease is often of considerable therapeutic value, and it is surprising to notice the intensity of the relief which

frequently ensues upon the bald statement that a disease is functional and not organic. The term Re-education has been further extended to the training in active movement of a limb paralysed from either organic or functional causes, or to the training of control of members of the body which are the subject of abnormal movements, as for instance in habit spasm, or to training in the relaxation of muscles habitually maintained by some patients in a state of functional hypertonus.

Like re-education, Persuasion involves a belief that the patient's views of his disorder and its effects upon him are faulty and that the correction of these will eventuate in a relief of his symptoms. The term Persuasion possibly indicates that the patient's mental condition is due to conscious and intellectual processes and that ratiocinative effort on the part of the physician will correct them if in error. It is, however, probably seldom that persuasion used therapeutically amounts to more than authoritative affirmations made in virtue of the physician's specialised knowledge. Fully to explain his pathological state to a patient would obviously involve in him a considerable amount of such technical knowledge as he does not as a rule possess, and in so far as this knowledge is wanting so far is the argument of the physician removed from the realm of reason. In practice, persuasion, like re-education, resolves itself into an endeavour to secure a fresh orientation of the patient's affections or emotions by inducing him to forget or at least to minimise his symptoms, to think and to act with resolution and courage, and to devote a large part of his thoughts and activities to the interests of others.

Unlike re-education and persuasion, which are avowedly addressed to that part of the patient's mind which is conscious or which can readily be brought into consciousness, a third method of psychotherapy, which usually passes under the name of Suggestion, seeks to influence the tendencies to imitate, to believe, to do what he is told, which are so universal among men, but whose existence in himself is rarely acknowledged or recognised by the average individual. These tendencies, even if not instinctive, are among the very earliest acquisitions of mental life, and one or other at least of them will be found in every one, though they are not in every one capable of exploitation for therapeutic purposes. There is no system of therapy, whether it be confessedly miraculous or mysterious, or mental or physical, which does not to a greater or less extent seek to make use of such authoritative powers as it can muster and by virtue of these to impose itself upon those patients who may seek its help. Successful therapy founded upon pure cognitions, although the dream of the man of physical science, is to-day unknown, and the healer who acquires the confidence of his patient, who induces the patient to do what he is bid and who is emphatic as to the merits of his mode of treatment, will often do more good than the scientist who endeavours to carry his patient with him along a path of pure heuristic ratiocination. The method of suggestion has to some extent been an attempt to legitimatise the frank appeal of the charlatan to the gullibility and gregarious imitativeness of the individual, and its successes have largely been due to the ordered and restrained use of such an appeal. But whereas the charlatan indiscriminately makes use of his unflattering generalisations and applies his method to all without any previous inquiry as to its suitability to individual cases, the psychiatrist endeavours by mental analysis to discover

in his patient those habits and lines of automatic working which, if they are of value, he can set to work or strengthen by his suggestions or which, if they are noxious, he can seek to impede or to obstruct. In education, re-education and persuasion it is sought to generate in an individual ideas and new lines of thought which may be of use to him; in suggestion it is sought to arouse, to stimulate and to render preponderant already existing, but latent, trends of thought. In practice the genesis of new ideas or excitation of such as already exist is often confused, for who, indeed, save possibly after a most profound, extensive and long-continued analysis can ascertain precisely when an idea first entered into a patient's mind? But so far as suggestion is practised as such, so far should its particular objects, as above set forth, be borne in mind.

Hypnotism, or the induction of a state resembling somnambulism, often, but not always, renders a patient more suggestible and is therefore used as an adjuvant to suggestion. In some persons, the state may be induced on the word of command or on command associated with some such physical act as looking intently at a small glittering object, or listening to a monotonous sound, or feeling repeated stroking or passes about the face and head. When the state has been induced desirable suggestions are made. A distinction should be made between the hypnotic state and one of mere drowsiness into which complacent patients will often pass as an act of polite acquiescence in the injunctions of the physician.

Merely to catalogue the affections in which hypnotism and suggestion have claimed successes would not be profitable, and it must suffice to set forth that affections of purely psychic origin are those that are most amenable. It should be remembered that such may include sensory disturbances, such as headaches or widely distributed neuralgic pain; motor disturbances, such as paralysis, spasm or abnormal movement; or disorders of various systems, for instance, indigestion, breathlessness or palpitation. The patient, however, must have some insight into his own morbid state and an honest intention of submitting himself to treatment. Disorders of physical origin frequently have secondary symptoms grafted upon them, and these also may sometimes be ameliorated.

Auto-suggestion may here be referred to since it has its uses in medical practice and looms largely in certain forms of extra-medical therapy. Auto-suggestion usually means that the patient has been recommended to suggest to himself that he is getting better of his ills, or that he has no ills, or indeed that there are no such things as ills to have. From any point of view, save that of a spurious "science," it is plainly essential that, before telling a patient that he is getting better, or that he has nothing the matter with him, the medical practitioner should make himself as sure as he possibly can be that the event will not falsify his forecast. In this matter, the charlatan, from the very limitations of his knowledge, has a distinct advantage over the man of science and does, indeed, with his more emphatic assurance, induce a hopeful expectancy of health. The medical practitioner, when he has by examination satisfied himself, if he can, that not even an obscure auto-intoxication, or profound endocrine disharmony, or elaborately symbolised mental complex, is at the root of the patient's disorder, may with profit counsel the patient to turn his thoughts from notions of disease, to break himself of the habit of thinking he is unwell and to create the habit of thinking

he is well. Auto-suggestion as expounded by its more scientific professors does not seek to influence health through the will but through processes regarded as taking place in the "sub-conscious," or the "unconscious." Hence the exhortation mechanically to repeat sentences asserting an expectation of improvement in health, day by day, for a prescribed number of times.

Such are the main outlines of the more important methods of psychotherapy. There are others of miraculous, mysterious or metaphysical origin which can scarcely be considered as within the scope of the present work, but perhaps it may not be wholly out of place to allude to the enormous succour that religion may bring to any form of therapy, even the most physical.

CERTIFICATION

When for various reasons it has been decided to certify a patient suffering from mental symptoms, the course most usually followed is to obtain two medical certificates, one of which is, where possible, under the hand of the patient's usual medical adviser. For reasons which will be obvious, the persons described in the following list are not competent to sign. The petitioner, whose functions we shall presently consider, the superintendent, proprietor or medical attendant of the asylum, hospital or house to which it is proposed the patient shall go; any person interested in the payment made for the patient; the husband or wife, father or father-in-law, mother or mother-in-law, daughter or daughter-in-law, son or son-in-law, brother or brother-in-law, sister or sister-in-law, the partner or the assistant of any of the foregoing persons. It is further provided that the medical practitioners signing the certificates must not be in partnership, nor one of them the assistant of the other; nor must they be related to one another as father, father-in-law, mother, mother-in-law, son, son-in-law, daughter, daughter-in-law, brother, brother-in-law, sister or sister-in-law. It is simpler to fill in the printed formula, which can be procured of a law stationer, than to write the certificate in full. The blank certificates set forth in detail the information required by the Board of Control, and the directions should be carefully followed. It should also be particularly borne in mind that the facts, as observed, which indicate insanity are to be set forth. The inference of the practitioner from the facts or his diagnosis are, for the purposes of the certificate, of no value or interest. For example, to write that a patient has general paralysis is valueless, for one suffering from general paralysis has not necessarily mental symptoms. To write that a patient says he is Emperor of the World is to report a fact indicative of insanity, and is of importance, while it is, on the other hand, of no value for the purposes of certification, whether such a delusion is a symptom of general paralysis or of paranoia or of some other form of mental disorder. If the detailed directions printed on the form be not scrupulously followed, the certificate will be returned for correction by the Board of Control. The medical practitioners signing the certificates must gather the evidence for their certificates in interviews with the patient apart from each other. Certificates must be signed and completed within seven clear days from the date of the interviews.

The person who carries through the business of certification is called

the petitioner, and should be the nearest available next-of-kin to the patient. If a relation be not available a friend or man of business may act. The petitioner has to fill two forms, one the petition and the second the statement. The petition is a request to a judicial authority to order the reception of the patient in an asylum, in a licensed house or in the house of some one undertaking the care of a single patient. The statement consists of a description of the patient's civil state, religion, previous history and of a few other particulars of like nature. The petitioner must have seen the patient within fourteen days of the presentation of the petition, and the petition must be presented not more than seven clear days after the date of the medical examination. The Judicial Authority in England may be a Stipendiary Magistrate, a County Court Judge or a Justice appointed for the purpose. On the presentation of the petition and the medical certificates, the Judicial Authority makes an order for the reception of the patient in the institution or house chosen for him. The Judicial Authority does not necessarily see the patient, but may do so. On medical grounds it is usually undesirable that such an interview should take place, for the intervention of one who does not know how to talk to or deal with a person of unsound mind frequently leads to the latter's detriment. When the order has been signed the legal requirements for the reception of the patient are fulfilled. The patient must be received within seven clear days of the date of the order, or the whole process is annulled and has to be undertaken *de novo*.

If the patient's condition be such that it is deemed desirable that a more expeditious process than that described above should be adopted, an urgency order may be made. The order is in these circumstances made by the nearest available next-of-kin, or by a friend, and is supported by only one medical certificate. The relative or friend making the order must have seen the patient within two days of the order, and the latter must be received within two days of the date of the medical examination. Upon such an order a patient may be detained within an asylum, or house, for seven days from the date of the order, but within that period all the papers required by the normal method of petition and certification must be completed.

In dealing with pauper patients, it is best for the relations or friends to obtain the services of the relieving officer of the district where the patient is domiciled. This officer may act by means of Summary Reception Orders as follows.

When any constable, relieving officer or overseer has knowledge that any person, whether or not a pauper, wandering at large, is a lunatic, it is his duty to take such person before a Justice. Or a Justice may upon information order a constable, relieving officer or overseer to bring an alleged lunatic before him. The Justice then calls upon a medical practitioner to examine and, if necessary, certify, and orders the reception of the lunatic in an institution.

It is the duty of a constable, relieving officer or overseer if satisfied it is for the public safety, or for the welfare of an alleged lunatic, to remove such lunatic to the workhouse of the Union. The Master of the workhouse may detain the alleged lunatic for not more than three days, and before the expiration of that time proceedings as already described must be taken by the constable, relieving officer or overseer.

When the Medical Officer of a Union has knowledge that a pauper resident within his district is a lunatic, it is his duty to give notice to the relieving officer or overseer, who, in his turn, informs a Justice, who orders the relieving

officer or overseer to bring the lunatic before him. It is further the duty of a constable, relieving officer or overseer, if it come to his knowledge that a person, not a pauper, and not wandering at large, is not under proper care and control or is being neglected, to give information under oath to a Justice. The Justice thereupon authorises two medical practitioners to examine the patient, and if necessary to certify. When the person is certified, the Justice makes an order that he shall be placed under care.

If a Justice be satisfied, in any case where a summary reception order might be made, that it is expedient a lunatic should forthwith be placed under care, he may make an order for the lunatic to be taken to a workhouse, but an order so made does not authorise detention for more than fourteen days.

When the question of the sanity of persons of property is raised an Inquisition in Lunacy may be held before a Master in Lunacy or a Judge of the High Court and a Jury. The sanity of the patient and his fitness to look after himself and his property are determined by this tribunal. If he be found unfit to look after himself, a Committee of his person is appointed, and if he be found incapable of looking after his property, a Committee is appointed to attend to it. This method is an expensive one.

A patient may also be certified by order of the Board of Control. In such a case, two or more members of the Board visit the alleged lunatic, not being in an institution or workhouse, and, if they think fit, call in a medical practitioner to examine the patient. If the practitioner certifies, the members of the Board may order the patient to be received in an institution.

It is to be understood in all cases that the medical practitioner who signs a certificate is in very much the same position as a witness who gives evidence in a court of law. The Authority which, according to its discretion, acts or does not act upon the evidence before it, is a Judicial Authority.

TESTAMENTARY CAPACITY

The power to make a will must obviously depend upon the possession of certain mental faculties. From the legal point of view, an individual must have a "disposing mind." His memory must be sufficiently good to enable him to understand the nature and extent of his property, and to remember those who by relationship or otherwise may be considered to have claims upon him. He must also be of sufficient intelligence to understand what a will is, and to appreciate the effect of what he is doing when he makes one. He should be capable of weighing the claims of various persons, and the reasons for the exclusion of some from, and the inclusion of others in, his will. He should not suffer from delusions which may affect his judgment in this respect. The testator should also have a "disposing will," that is, he should be capable of exercising a free and independent choice, unswayed by the suggestions, recommendations or persuasions of interested persons.

as a cause of jaundice, 616
as a sequel of gall-stones, 659
intestinal, sites of, 594.
lupus in relation to, 1335.
of brain, 1407.
of the colon. *See* Colon, cancer of the, of liver, 646-650.
of the œsophagus. *See* under Œsophagus, of the peritoneum, 692, 693.
of the stomach, achylia in, 554.
hæmatemesis in, 553.
And see under Stomach.
- Cancerum oris**, 491.
- Capillary bronchitis**, 1036.
pulsation in aortic incompetence, 812.
in hyperthyroidism, 461.
- Caput Medusæ**, 634.
- Carbohydrate dyspepsia, Intestinal**, 582-584.
etiology of, 582, 583.
diagnosis of, 583, 584.
digestive ferments in relation to, 582.
enterococci in, 583.
symptoms of, 583.
treatment of, 584.
excess in relation to diabetes mellitus, 401.
- Carbon dioxide**, reduced excretion of, in ketosis, 406.
- monoxide**, 375, 376.
action of, 376, 377.
poisoning, 375-379.
etiology of, 376, 377.
after-treatment of, 379.
diagnosis of, 378.
industrial risks of, 376.
post-mortem appearances in, 377.
symptoms of, 377.
treatment of, 378, 379.
- Carbuncle**, 1300.
vaccine treatment of, 43.

- Carbuncles** in diabetes, 410.
in plague, 171.
- Carcinoma.** *See under* Cancer.
- Cardiac.** *See also under* Heart.
asthenia in toxemia, 50.
asthma, 753, 1053.
in acute pericarditis, 878.
in infarction of heart, 861.
syphilis as a cause of, 890.
- cells** in hyperemia and oedema of lungs, 1062.
- cycle**, the, 744.
time occupied by phases of, 744.
- overstrain**, primary, 901-903.
etiology of, 901.
diagnosis of, 902.
prognosis of, 902.
symptoms of, 901, 902.
treatment of, 902, 903.
- valvular disease**, chronic. *See* Valvular disease of the heart.
- Cardiogram**, 745, 746.
inverted, 745.
negative, 745.
analysis of, 746.
positive, 745.
analysis of, 745, 746.
- Cardiolysis**, 885.
- Cardiospasm**, 507-510.
And see Achalasia of the cardia.

and varicella, 280, 1342.
caused by arsenic, 1341.
from lesion of geniculate ganglion, 1385, 1386.
of cornea, 1381.
of fifth nerve, 1381.
symptoms of, 1342.
treatment of, 1342.
- Heterophyes heterophyes**, 331.
as a cause of diarrhoea, 579.
- Heterophylasis**, 331, 332.
- Hexamine** in cerebro-spinal fever, 168.
value of, in *B. coli* infections, 84.
- Hibernation** in relation to production of heat, 3.
- Hiccough**, epidemic, 1165, 1166.
in lethargic encephalitis, 148, 1165.
simple, 1165.
- Hill's** method of giving oxygen, 772.
- Hill, Leonard**, his "Kata" thermometer, 358, 359.
- Hill diarrhoea**, 579.
- Hilum tuberculosis**, 1100, 1101.
- Hippuric acid** in urine, 1179.
- Hirschfeld's bronchioles**, 1091.
- Hirschsprung's disease**, 600.
And see Achalasia of pelvi-rectal and anal sphincters.
- Histoplasma capsulatum**, 183.
- Histoplasmosis**, 183.
- Hoarseness**, continued, in children, 1013.
in acute tracheitis, 1024.
in chronic laryngitis, 1006.
in laryngeal paralysis, 1017.
in laryngeal tuberculosis, 1010.
in malignant laryngeal tumours, 1013, 1014.
- Hodgkin's disease**, 699.
See Lymphadenoma.
- Hofmann's bacillus**, 91.
sign in tetany, 1679.
- Hooklets**, hydatid, 336.
- Holder's** experiments on prophylactic vaccines in rabbits, 32.
- Horse serum**, toxic idiopathy to, 24.
- Hour-glass stomach**, 558-560.
aetiology of, 558, 559.
- Hour-glass stomach**, gastric ulcer in relation to, 546, 558, 559.
orthostatic, 559.
spasmodic, 521, 522, 559.
symptoms of, 559, 560.
treatment of, 560.
- Humidity of atmosphere** in relation to heat stroke, 358.
- Humoral theory of immunity**, 15.
- Hunger-pain**, 546.
- Hutchinson's teeth**, 205.
- Hyaline degeneration** of lymphatic glands in lymphadenoma, 700.
- Hydatid cysts**, 335, 336.
compressing the cord, 1502.
development of, 335, 336.
of liver, 645.
rupture of, 646.
of lungs, 1120.
of mediastinum, 1176.
of peritoneum, 691.
disease of heart and pericardium, 894.
of lung, 1120, 1121.
of pleura, 1162.
fluid, 336, 644.
parapleural, 1162.
thrill, 336, 645.
- Hydatids** in relation to jaundice, 616, 645.
- Hydrarthrosis**, intermittent, 1256, 1257.
periodic, with circumscribed oedema, 978.
- Hydroa æstivale**, 1286.
hæmatoporphyrinuria in, 1286.
gestationis, 1329.
- Hydrocephalic cry**, the, 1435.
type of idiocy, 1741.
- Hydrocephalus**, 1416-1425.
aetiology of, 1417.
and syphilis, 1417, 1425, 1440.
cerebro-spinal fluid in, 1417, 1418, 1419, 1420.
clinical groups of, 1416.
congenital deformities associated with, 1417.
diagnosis of, 1424.
in cerebro-spinal fever, 158, 166, 169.
in post-basic meningitis, 158.
injury in relation to, 1417.
pathology of, 1417-1421.
prognosis of, 1424, 1425.
symptoms of, 1421-1424.
syphilis in relation to, 1440.
treatment of, 1425.
- Hydrochloric acid**, excretion of, into stomach, 402.
in relation to bacterial activity in the stomach, 486, 530, 531.
of gastric juice, action of, on bacteria, 486.
- Hydrogen ion** concentration of blood, 401, 402, 403.
- Hydronephrosis**, 1231, 1232.
aetiology of, 1231.

- Hydronephrosis**, course of, 1232.
 diagnosis of, 1232.
 intermittent, 1232.
 pathology of, 1231.
 symptoms of, 1231, 1232.
 treatment of, 1232.
- Hydropericardium**, 886.
 aetiology of, 886.
 symptoms of, 886.
- Hydrophobia**, 306-308.
 aetiology of, 306, 307.
 diagnosis of, 307, 308.
 incubation period of, 307.
 invasion stage of, 307.
 paralytic stage of, 307.
 prognosis in, 308.
 specific therapy of, 308.
 stage of excitement in, 307.
 symptoms of, 307.
 transmission of, 307.
 treatment of, 308.
 virus of, 307, 308.
- Hydrothorax**, 1153, 1154.
 aetiology of, 1153.
 characters of fluid in, 1153.
 pathology of, 1153, 1154.
 symptoms of, 1154.
 treatment of, 1154.
- Hymenolepis nana**, 335.
- Hyperæsthesia**, cutaneous, in relation to
 gastralgia, 535.
 in acute pericarditis, 878.
 in hydrophobia, 307.
 in tabes, 1197.
 of skin, 1277.
 in herpes zoster, 1342.
 pharyngeal, 501.
 right iliac, in acute appendicitis, 609.
- Hyperalgesia** in trench fever, 304.
- Hyperbilirubinæmia**, 618.
- Hyperchlorhydria**, 524, 525.
 in relation to gastric and duodenal ulcer,
 524, 549.
 physiological, 524.
 reflex, 524.
 symptoms of, 525.
 toxic, 524.
 treatment of, 525.
- Hyperglycæmia** in anoxæmia, 353.
- Hyperidrosis**, 1275, 1276.
 caused by arsenic, 1321.
 in erythromelalgia, 980.
 situations affected by, 1276.
- Hyperkeratosis**, 1274.
 from arsenic, 1321.
 from bromides, 1321.
 in pityriasis rubra pilaris, 1346.
 of soles in arsenical poisoning, 1662.
- Hypernephroma**, 1233, 1234.
- Hyperpiesia**, 944, 945, 969, 970, 971.
 and chronic interstitial nephritis dis-
 tinguished, 970, 971.
- Hyperpituitarism** in acromegaly, 476.
- Hyperpncea**, 982.
 in acidæmia, 402.
 in diabetic coma, 402, 410.
- Hyperpyrexia** from heat, 359, 360.
 in blackwater fever, 226.
 in epidemic diarrhoea in children, 576.
 in febrile diseases, induced by heat-
 stroke, 359.
 in influenza, 128.
 in tetanus, 106.
 in typhus fever, 284.
 rheumatic, 295, 296, 300.
- Hyperpyrexial fever**, 328.
- Hyper-resonance of chest**, 983.
- Hypersecretion**, gastric, 525.
 and hypertonus, 520, 521.
 in relation to appendicitis, 613.
 paroxysmal, 525.
And see Hyperchlorhydria.
- Hypersthenic gastric diathesis**, 521, 524, 543.
 in relation to gastric and duodenal
 ulcer, 543.
 short stomach in the, 672.
- Hypertension**, arterial, 969-973.
 aetiology of, 970.
 diagnosis of, 970, 971.
 symptoms of, 970.
 treatment of, 971-973.
- Hyperthermia**, 1.
- Hyperthyroidism**, 460-466.
 aetiology of, 460, 465.
 basal metabolism in relation to, 399, 410,
 462.
 cervical sympathetic in relation to, 1379.
 circulatory disorders in, 461.
 diagnosis of, 463.
 diarrhoea in, 463, 570.
 electro-cardiograms in, 931.
 in relation to hypertrophy of heart,
 870.
 in relation to neurasthenia, 1588.
 low blood-pressure in, 968.
 mental disorders in, 1721, 1722.
 pathology of, 459, 460, 461.
 prognosis of, 463.
 radiotherapy of, 465.
 relapses in, 463.
 surgical treatment of, 465, 466.
 symptoms of, 461-463.
 treatment of, 463, 464.
- Hypertonus of stomach**, 520, 521.
And see Stomach.
- Hypertrichosis**, 1365.
- Hypertrophic sclerosis of brain**, 1739.
- Hypertrophy**, cardio-vascular, 944.
 of the heart, 869-872.
 aetiology of, 870.
 concentric, 869.
 diagnosis of, 872.
 dilatation with, 869, 871, 872.
 electro-cardiogram of, 919, 920.
 eccentric, 869, 873.
 false, 867.

- Hypertrophy of the heart** in chronic parenchymatous nephritis, 1202.
 in granular kidney, 1208.
 in mitral regurgitation, 849.
 in pulmonary incompetence, 852.
 in relation to compensation, 836, 837.
 in secondary contracted kidney, 1203.
 kinds of, 869.
 pathology of, 870.
 pericardial adhesions in relation to, 883.
 prognosis of, 872.
 symptoms of, 870-872.
 treatment of, 872.
of left ventricle, signs of, 839, 871.
of the os calcis, endemic, 324.
of the thymus. *See* Thymus, hypertrophy of.
- Hyperventilation** in relation to epilepsy, 1530, 1531.
- Hypnotics** for delirium tremens, 1702.
 in cardiac failure, 773, 774.
- Hypnotism** in psychotherapy, 1755.
- Hypochlorhydria**, 525-529.
- Hypochondria**, 1587.
- Hypoglycæmia**, 408.
 symptoms of, 408.
 treatment of, 409.
- Hypopituitarism** in dystrophia adiposogenitalis, 478.
- Hyposecretion** of gastric juice, 525.
And see Achylia gastrica.
- Hyposthenic habitus**, long stomach in the, 672.
- Hypotension**, arterial, 968, 969.
 ætiology of, 968, 969.
 symptoms of, 969.
 treatment of, 969.
- Hypothyroidism**, 466.
And see Myxœdema.
 anidrosis in, 1274.
 basal metabolism in relation to, 467.
 in relation to infantilism, 480.
- Hypsobia nosophora**, 333.
- Hysteria**, 1574-1585.
 absence of signs of organic disease in, 1574.
 ætiology of, 1574.
 course and prognosis of, 1583, 1584.
 defence, 1577.
 diagnosis of, 1582, 1583.
 disorders of hearing in, 1578.
 disorders of sensibility in, 1578, 1579.
 electrical reactions in, 1577.
 mental condition of, 1574, 1577.
 modern conceptions of, 1575-1577.
 paralysis in, 1579, 1580.
 diagnosis of, 1579, 1580, 1583.
 pathology of, 1575-1577.
 prognosis in, 1529, 1574, 1583, 1584.
 psycho-analytic treatment of, 1585.
 reflexes in, 1579, 1580, 1582.
 retention, 1576.
- Hysteria**, speech disorders in, 1462, 1578.
 suggestion treatment of, 1584.
 symptoms of, 1577-1582.
 treatment of, 1584, 1585.
 visual disorders in, 1577, 1578.
 war experiences in relation to, 1574, 1575.
- Hysterical pseudo-constipation**, 566.
 fits, 1581, 1582.
 differential diagnosis of, 1583.
 paralysis, 1579, 1580.
 polyuria, 479.
 pseudo-angina, 911.
 spasm of œsophagus, 506.
 spine, 1580.
 tremor, 1581.
- Ichthyosis**, 1274, 1275.
 ætiology and pathology of, 1274.
congenita, 1274.
hystrix, 1275, 1360.
 symptoms of, 1274, 1275.
 treatment of, 1275.
- Icteric fever** of Carter, 187.
- Icterus**. *See* Jaundice.
gravis, 311, 380, 382, 383, 615.
 symptoms of, 311, 380.
 toxic symptoms after salvarsan remedies simulating, 380.
neonatorum, familial, 622.
neonatorum, 620.
- Idiocy**, 1737, 1745.
 ætiology of, 1738.
amaurotic family, 1478, 1479.
 congenital, 1477.
cretin type of, 1738, 1739, 1740, 1741.
 definitions of, 1737, 1738.
hydrocephalic type of, 1741.
 in cerebral type of acute anterior poliomyelitis, 144.
microcephalic, 1477, 1741.
mongol type of, 1738, 1739, 1740.
 pathology of, 1738, 1739.
 restless, 144, 1477.
 symptoms of, 1739, 1740.
- Idioglossia**, 1472.
- Idiopathic anæmia**. *See* Anæmia, pernicious.
- Ileal stasis** in chronic appendicitis, 613.
- Ileo-cæcal sphincter**, rôle of, in relation to infection, 586.
- Ileo-colitis**, acute, 575.
- Ileo-colostomy** for cancer of colon, 597.
- Ileus, chronic duodenal**, 674.
- Imagination**, activity of, in mania, 1718, 1719.
- Imbecility**, 1737.
 moral, 1742, 1743.
- Immune therapy**, 24-49.
 choice of remedy in, 28.
- Immunisation**, active, 19.
- Immunity**, 14-24.
acquired, 18-24.
 active, 19.
 in relation to vaccine therapy, 19.

- Immunity, active**, methods of producing.

 the pulmonary, 1113, 1116.
- Mycosis fungoides**, 1352, 1353.
- Mydaleine**, a ptomaine body, 386.
- Myelin kidney**, the, 1194.
- Myelitis**, acute syphilitic, 1487.
 funicular, 1617.
- Myelocytes**, 705.
- Myelomalacia**, 1614, 1615.
 as terminal phenomenon in progressive diseases, 1615.
 from pressure, 1614, 1615.
 from traumatism, 1614.
 inflammatory conditions causing, 1615.
- Myelopathic polycythæmia**, 707.
- Myiasis**, 342-344.
 dermal, 342-344.
 intestinal, 344.
- Myocardial degeneration**, atheroma in relation to, 941.
 in relation to angina pectoris, 906, 909.
 failure in typhoid, 68.
- Myocarditis**, acute, 857-860.
 aetiology of, 857.
 diagnosis of, 859.
 pathology of, 857.
 prognosis of, 859, 860.
 symptoms of, 857, 859.
- chronic interstitial**, 867-869.
 aetiology of, 867.
 diagnosis of, 868, 869.
 pathology of, 867, 868.
 prognosis of, 869.
 symptoms of, 868.
 treatment of, 869.
- diphtherial**, 857, 858, 859.
influenzal, 858, 859.
rheumatic, 295, 857.
suppurative, 857.
toxic, 51.
tuberculous, 857.
 varieties of, 857.
- Myocardium**, abscesses in, 857.
 affections of in typhoid, 63, 68.
 affections of the, importance of, 856.
and coronary arteries, diseases of the, 856-876.
- Myocardium, chronic disease of**, 862-869.
 degeneration of, in coronary disease, 860.
 effect of diphtheria on, 92, 96.
fatty degeneration of the, 864-867.
 aetiology of, 864.
 diagnosis of, 866.
 pathology of, 864, 865.
 prognosis of, 866, 867.
 symptoms of, 865, 866.
infiltration of, 862-864.
 aetiology of, 862.
 diagnosis of, 863.
 pathology of, 862, 863.
 prognosis of, 863.
 symptoms of, 863.
 treatment of, 863, 864.
fibrosis of, 867.
 importance of condition of, in prognosis, 757.
 in aortic incompetence, 836, 844.
 syphilis of, 888, 889.
- Myoclonus**, 1561-1563.
 aetiology of, 1561, 1562.
 course and prognosis of, 1563.
 diagnosis of, 1562, 1563.
 epileptic, 1532, 1562.
 symptoms of, 1562.
 treatment of, 1563.
- Unverricht's**, 1541.
- Myoidema**, 1100.
- Myokimia**, 1562, 1632.
- Myoma of skin**, 1358.
- Myomalacia cordis**, 941.
- Myopathic atrophy**, 1686.
 types of, 1686.
face, 1675.
- Myopathies**, the, 1686-1690.
 aetiology of, 1686, 1687.
- Myopathy**, aetiology of various types of, 1688, 1689.
 diagnosis of, 1689.
 prognosis of, 1690.
 symptoms of, 1689.
 treatment of, 1690.
- Myosalvarsan** in syphilis, 207.
- Myosis**, diagnostic significance of, 1378.
pontine, 1404.
- Myositis**, 1260, 1261.
 fibrous, in alcoholic neuritis, 1662.
 non-suppurative, 1261.
ossificans progressiva, 1261.
 suppurative, 1260, 1261.
- Myotonia**, relation of tetany to, 1678.
atrophica, 1674.
And see Dystrophia myotonica.
- congenita**, 1672, 1673.
 aetiology of, 1672.
 pathology of, 1672, 1673.
 symptoms of, 1673.
 treatment of, 1673.
- Myotonic reaction of Erb**, 1673, 1675.
- Myophobia**, 1568.
- Myxœdema**, 466-468.

- Myxœdema**, ætiology of, 466.
 age-incidence of, 466.
 diagnosis of, 467, 468.
 pathology of, 466, 467.
 prognosis of, 468.
 sex-incidence of, 466.
 symptoms of, 467.
 treatment of, 468.
And see Hypothyroidism.

 capillary, 1359.
 cavernous, 1359.
 hyperkeratotic, 1360.
 linear, 1360.
 lymphatic, 1360.
 pigmentary, 1360.
 stellate, 1359.
 treatment of, 1360.
 vascular, 1359.
- Nævo-carcinoma**, 1360.
- Nagana**, 233.
- Nails**, affections of, in congenital syphilis 204.
 affections of, in hypertrophic pulmonary arthropathy, 1263.
 affections of, in syphilis, 197, 198.
 eczema of, 1290.
 favus of the, 1314.
 in chronic arsenical poisoning, 369.
 lesions of, due to arsenic, 1321.
 reeded, in hysteria, 1581.
 ringworm of the, 1313.
 symptoms of, 1313.
 treatment of, 1313.
- Naja tripudians** (cobra), 345.
- Narcolepsy**, 1546, 1547.
 after encephalitis lethargica, 1547.
- Nares**, plugging the, 991.
- Nasal causes of asthma**, 1050.
 diphtheria, 95, 99, 990.
 douching, 987, 988.
 feeding, 1716.
 irritation in intracranial tumour, 1412.
 obstruction from adenoids, 999.
 septum, angio-fibroma of the, 990, 997.
 idiopathic perforation of, 988.
- Nascent iodine treatment of nasal tuberculosis**, 997.
 of pulmonary tuberculosis, 1110.
- Naso-pharyngitis, chronic**, vaccine treatment of, 36.
- Naso-pharynx**, diseases of the, 998-1001.
 tumours of, 1001.
- Nauheim exercises for fatty heart**, 864.
 treatment of cardiac disease, 761.
- Nausea**, 530.
 ætiology of, 530.
 hysterical, 530.
 in pregnancy, 530.
- Necator americanus** as human parasite, 339.
- Neck**, actinomycosis affecting, 178.
- Necrosis of tissue** as result of bacterial infection, 13.
- Negativism** in catatonias, 1730, 1731.
 in hebephrenia, 1730.
- Negri bodies** specific to rabies, 307.
- Negroes**, rarity of chorea among, 1551.
 sickle-celled anæmia in, 716.
- Nematodes**, diseases due to, 336-342.
- Neo-arsphenamine**, 207.
- Neokharsivan**, 207.
- Neosalvarsan**, 207.
 method of administration of, 207, 209.
 211, 216, 217, 218.
- Neostam** in kala-azar, 231.
- Nephrectomy** in renal tuberculosis, 1227, 1228.
 in unilateral hydronephrosis, 1232.
- Nephritis**, 1192-1211.
 acute, 1195-1200.
 ætiology of, 1195, 1196.
 complications of, 1197, 1198.
 diagnosis of, 1198.
 epidemic form of, 1196.
 pathology of, 1196, 1197.
 prognosis of, 1198.
 symptoms of, 1197.
 toxic factors in, 1196.
 treatment of, 1198-1200.
 chronic interstitial, 1207-1211.
 ætiology of, 1207.
 complications of, 1209.
 diagnosis of, 1209.
 pathology of, 1207, 1208.
 prognosis of, 1209.
 symptoms of, 1208, 1209.
 treatment of, 1209-1211.
- chronic parenchymatous**, 1200-1202.
 ætiology of, 1201.
 pathology of, 1201, 1202.
 symptoms of, 1202.
 classification of, 1192, 1193.
 from use of mercury, 213, 214.
- glomerular**, in infective endocarditis, 828.

 treatment of, 1005, 1006.
Pericolic suppuration, B. coli in, 80.
Pericollitis sinistra, 598.
Perihepatitis, 686, 687.
 in cancer, 648.
 in cirrhosis of liver, 637.
 syphilitic, 642.
Perinephric abscess in typhoid fever, 71.
 suppuration, epidemic, 1224.
Perinephritis and perinephric abscess, 1224
 1226.
 aetiology and pathology of, 1224,
 1225.
 bacteriology of, 1224.
 course of, 1225.
 diagnosis of, 1225.
 symptoms of, 1225.
 treatment of, 1226.
Periodontitis, chronic, 485.
 And see Pyorrhoea alveolaris.

- Periostitis**, acute, arthritis in, 1248.
in paratyphoid fever, 78.
in secondary syphilis, 199.
- Peripheral neuritis**. *See* Polyneuritis.
- Periphlebitis**, 959.
- Perisplenitis**, 635.
- Peristalsis**, gastric, in pyloric obstruction, 517, 556, 557.
visible, 516, 517, 557.
- Peritoneal adhesions**, 684.
cause and sites of, 684, 685.
in relation to obstruction, 685.
cysts, 691, 692.
- Peritoneum**, cancer of the, 692, 693.
aetiology of, 692.
diagnosis of, 692.
pathology of, 692.
symptoms of, 692.
treatment of, 692, 693.
- diseases of the**, 677-696.
- Peritonitis, acute**, 677-684.
aetiology of, 678, 679.
bacteriology of, 678.
diagnosis of, 682.
fulminant, 679, 680.
generalised, 679, 680, 681, 682.
perforative, 683.
prognosis of, 682, 683.
sources of infection in, 678, 679.
spreading, 680, 683.
symptoms of, 679-682.
treatment of, 683, 684.
- adhesive**, 684-686, 688.
B. coli in, 80.
- chronic**, 684-686.
aetiology and pathology of, 684, 685.
obliterative, 688.
syphilitic, 687.
- diffuse chronic**, 686, 687.
aetiology of, 686, 687.
pathology of, 687.
symptoms of, 687.
- fibro-purulent**, 683.
- fibrous tuberculous**, 688.
- gonococcal**, 60, 681, 683, 684.
n acute appendicitis, 610, 611, 612.
n acute suppurative gastritis, 540.
n intestinal obstruction, 605, 606.
n paratyphoid fever, 78.
n relation to acute intestinal obstruction, 606, 607.
- in ulcerative colitis, 591.
indications for operation in, 683, 684.
- localised chronic**, 684-686.
symptoms of, 685, 686.
treatment of, 686.
- malignant**, 648, 692, 693.
paths of infection in, 678, 679.
- pelvic**, 684, 686.
- perforative**, in typhoid, 65, 67.
- pneumococcal**, 59, 680, 681.
encysted, 681.
path of infection in, 681.
- Peritonitis, pneumococcal**, symptoms of, 681.
staphylococcal, 678.
streptococcal, 681, 682.
source of infection, in, 682.
- tuberculous**, 687-691.
aetiology of, 687, 688.
ascitic form of, 689.
diagnosis of, 690.
in cirrhosis of liver, 637.
indications for operation in, 691.
loculated, 688, 689.
path of infection in, 687, 688.
pathology of, 688.
prognosis of, 690.
symptoms of, 688-690.
treatment of, 690, 691.
- Peritonsillar abscess**, 495, 496.
- Pernicious anæmia**. *See* Anæmia, pernicious.
- Peroneal muscular atrophy**, 1636-1639.
aetiology of, 1636.
course of, 1638.
diagnosis of, 1638, 1639.
pathology of, 1636, 1637.
prognosis of, 1639.
symptoms of, 1637, 1638.
treatment of, 1639.
- Perseveration**, 1474.
- Persuasion** in psychotherapy, 1754.
- Pertussis**. *See* Whooping-cough.

- Pfeiffer's bacillus**. *See* Bacillus *pfeifferi*.
- phenomenon**, 22.
- Phagedena**, tropical sloughing, 1367.
- Phagedenic ulceration** in syphilis, 194, 201.
- Phagocytes**, 16.
- Phagocytosis**, conditions of, 16.
in relation to chemiotaxis, 16.
in relation to immunity, 15, 16.
in relation to tetanus, 104.
- Phantasy**, 1694.
- Pharyngeal hyperæsthesia**, 501.
paralysis, 1392.
tonsil, 998.

- Pharyngitis**, acute catarrhal, 499.
 acute septic, 499, 500.
 symptoms of, 499, 500.
 treatment of, 500.
 atrophic, 501.
 chronic, 501, 502.
 ætiology of, 501.
 granular, 501.
 in atrophic rhinitis, 989.
 lateral, 501.
sicca, 501.
- Pharyngo-œsophageal sphincter**, achalasia of, 507.
- Pharynx**, diseases of the, 499-506.
 lupus and tuberculosis of the, 504, 505.
 syphilis of the, 502-504.
 symptoms of, 503.
 tumours of the, 505, 506.
 and **œsophagus**, **diverticula** of, 511, 512.
- Phenol-phthalein**, skin eruption due to, 1322.
-sulphone-phthalein test of renal efficiency, 1181.
- Phenoquin** in gout, 427.
- Phenyl-hydrazine** in polycythæmia, 708.
- Philip's** classification of tubercular stages, 1103.
- Phlebitis**, 959, 960.
 classification of, 959.
 gouty, 424, 959, 960.
 in relation to embolism, 960.
 in relation to thrombosis, 959, 960.
 infection in relation to, 959, 960.
 non-suppurative, 959.
 plastic, 959, 960.
 ætiology of, 959.
 symptoms of, 959.
 treatment of, 959, 960.
 varieties of, 959.
 post-operative, 959.
 puerperal, 959.
And see Phlegmasia alba.
- suppurative**, 960.
 ætiology of, 960.
 symptoms of, 960.
 treatment of, 960.
 traumatic, 959.
- Phlebogram**, 746-749.
- Phlebotomus argentipes** as possible vector of kala-azar, 228.
 fever, 315, 316.
 ætiology of, 315.
 diagnosis of, 316.
 prognosis of, 316.
 symptoms of, 316.
 treatment of, 316.
- papatasil**, 315.
 as possible vector of oriental sore, 231.
- Phlegmasia alba dolens**, 959.
And see Phlebitis, puerperal.
- Phobias** in neurasthenia, 1587.
 in psychasthenia, 1750.
- Phanation** (*argyrea*) disorders of, 1016-1019
- Phosphates** in urine, 1179.
- Phosphatic calculi**, 1228.
- Phosphoretted hydrogen**, poisoning by, 383.
- Phosphorus poisoning**, 380, 381, 382.
 fatty heart in, 864.
 symptoms of, 382.
- Photophobia** in measles, 241, 246.
 in cerebro-spinal fever, 154.
- Phrenic nerve**, anatomy and physiology of, 1641.
 evulsion of, 1112.
 lesions of, 1641.
 section for tuberculosis, 1112.
- Phrenicotomy** for bronchiectasis, 1060.

 types of, 6.
- Pyridin** in relation to pernicious anæmia, 1618.
- Pyrotherapy** in syphilis, 217.
- Pyuria**, 82, 1189.
- Quartan type of malaria**, 222.
- Quincke's disease**. *See* Angio-neurotic œdema.
- Quinidine**, 767-770.
 contra-indications to use of, 769.
 disadvantages of, 768, 769.
 dosage of, 770.
 effects of, 767.
 in auricular fibrillation, 767-770, 808, 809.
 in paroxysmal tachycardia, 818.
 indications for, 768, 809.
 risk of embolism and thrombosis in, 768.
 toxic symptoms from use of, 768.
- Quinine**, explanation of antipyretic action of, 6, 7, 9.
 hæmoglobinuria, 225.
 hydrobromide in hyperthyroidism, 464.
 in malaria, 223, 224.
 preparations in pneumonia, 1130.
- Quinophan** in gout, 427.
- Quinsy**, 495, 496.
 ætiology of, 495.
 complications of, 496.
 symptoms of, 495, 496.
 treatment of, 496.
- Rabbits** as carriers of infection in tularæmia, 175.
- Rabies**. *See* Hydrophobia.
- Radiography** of the chest, 985, 1100, 1101.
 of the intestines, 561, 562.
 of the kidney and ureter, 1182, 1223, 1225, 1229, 1232, 1234, 1239.
 of the stomach, 516, 517, 518.
- Radiotherapy** of throat diseases, 506.
- Radium dermatitis**, 1286.
 in hyperthyroidism, 465.
 in lupus of larynx, 1009.
 in new-growths of lung, 1119.
 needles, in malignant tumours of nose, 998.
 treatment of laryngeal tumours, technique of, 1015.
- Radon** in hyperthyroidism, 465.
 seeds, use of, in lymphadenoma, 702.
- Râles**, 984.
 bubbling, 984.
 crackling, 984.
 crepitant, 984.
 gurgling, 984.
- Rammstedt's operation** for congenital hypertrophy of the pylorus, 558.
- Rash** in cerebro-spinal fever, 154, 156.
 in congenital syphilis, 204.
 in dengue, 316, 317.
 in erysipelas, characters of, 56.
 in influenza, 124.
 in measles, 241, 242.
 in Oroya fever, 320.
 in rat-bite fever, 190.
 in rubella, 248.

Rash in scarlet fever, 253, 256.
in secondary syphilis, 199, 200.
in small-pox, 267-270, 271-273.
in spotted fever of the Rocky Mountains, 318.
in tsutsugamushi fever, 319.
in typhoid, 64.
in typhus, 284.

Rashes after diphtheria antitoxin, 102.
skin, in acute endocarditis, 821.

Raspberry tongue in scarlet fever, 254.

Rat-bite disease, 189.
fever, 189, 190.
aetiology of, 189, 190.
diagnosis of, 190.
pathology of, 190.
prognosis of, 190.
symptoms of, 190.
treatment of, 190.

Rat flea, 170.

Rats as disseminators of rat-bite fever, 189, 190.

as medium of infection of spirochaetosis
ictero-hæmorrhagica, 184.

in relation to plague, 170, 172.

Ray-fungus disease. See Actinomycosis.

Raynaud's disease, 974-977.

aetiology of, 975.
diagnosis of, 976.
paroxysmal hæmoglobinuria in, 1186.
pathology of, 975.
prognosis of, 976.
symptoms of, 975, 976.
treatment of, 97.

Reaction, focal, after vaccine inoculation
31, 32.
general, after vaccine inoculation, 31.
local, after vaccine inoculation, 31.
mixed, in progressive muscular atrophy,
1632.
of degeneration in poliomyelitis, 139.
of a fluid, in relation to H ion concentra-
tion, 400, 401.
to tuberculin, 48.

Recklinghausen's disease, 1358.

Recompression in the treatment of caisson
disease, 353.

Rectal administration of immune sera, 29.
crises in tabes, 1500.
treatment of, 1504.
examination, value of, in acute appendi-
citis, 610, 611.

Rectitis, epidemic gangrenous, 326.

Rectum, dyschezia in relation to the, 564.
565, 566, 567, 568.

lesions of, in schistosomiasis, 332, 333.

Red corpuscles, fragility of, in acholuric
jaundice, 623.

Red-light treatment of small-pox, 275.

Red mite dermatitis, 345.

Re-education in psychotherapy, 1753, 1754.

Reflex epilepsy, 1534.

grasping, 1400.

Reflexes, abdominal, diminution of, in
lesions of hemispheres, 1400.

exaggerated, in trench fever, 305.

in acute poliomyelitis, 139, 140.

in apoplexy, 1452.

in cerebro-spinal fever, 154.

in chorea, 1557.

in dementia præcox, 1729.

in diabetic neuritis, 1666.

in disseminate sclerosis, 1508.

in Friedreich's ataxy, 1519.

in general paralysis of the insane, 1492.

in hydrocephalus in children, 1423.

in hysteria, 1579, 1580, 1582.

in interstitial neuritis, 1652, 1654.

in lethargic encephalitis, 149, 150.

in localisation of spinal cord lesions, 1597.

in myasthenia gravis, 1683.

in progressive muscular atrophy, 1632,
1633.

in sciatica, 1654.

in spastic paraplegia, 1593.

in subacute combined degeneration,
1620, 1621, 1622.

in syringomyelia, 1606.

in tabes, 1498, 1500, 1501.

Refractory stage of conductivity, 742, 743.

Regurgitation of food, 523.

Relapsing fever, 186-188.

aetiology of, 186.

African, 188.

American, 188.

Asiatic, 187, 188.

types of, 187.

Central African, 188.

complications and sequelæ of, 187,
188.

diagnosis of, 187, 188.

distribution of, 186, 188.

European form of, 187.

lice in relation to, 186, 187.

mortality in, 187, 188.

path of infection in, 186.

pathology of, 186.

prognosis of, 187, 188.

Somaliland variety of, 188.

symptoms of, 187, 188.

treatment of, 187, 188.

Religious factor in delusional insanity,
1736.

Remissions in leukemia, 720, 722.

in undulant fever, 173.

Renal calculi, 1228-1230.

aetiology of, 1228.

contra-indications to operation in,
1230.

diagnosis of, 1229.

in osteomalacia, 1267.

pathology of, 1228, 1229.

prognosis of, 1230.

symptoms of, 1229.

treatment of, 1230.

changes in chronic alcoholism, 365.

- Renal cirrhosis** in relation to hypertrophy of heart, 872.
colic, 1229.
 treatment of, 1230.
crises in tabes, 1501.
disease in relation to cerebral thrombosis and hæmorrhage, 1448.
 papilloedema in, 1410.
 relationship of cardio-vascular hypertrophy to, 944.
 dwarfism, 481, 1203.
function, estimation of, 1180-1182.
glycosuria, 420, 421.
symptoms in arterial hypertrophy, 945
 vein, thrombosis of, 1191, 1192.
Replacement fibrosis of the liver, 380, 382.
Repression, 1576.
Resection of colon for cancer, 597.
Resistant stupor in cerebro-spinal fever, 155.
Resonance, pulmonary, varieties of, 983.
 vocal, 985.
Respiration, disturbed, in intracranial tumour, 1412.
 in relation to sinus irregularity, 785.
 irregular, in cerebro-spinal fever, 154.
Respiration-rate in fever, 8.
Respiratory centre, function of, in regulating reaction of blood, 401.
 complications of typhus fever, 285.
 disorders in rickets, 445.
 effects of high altitudes, 354.
 movements in emphysema, 1076.
 quotient, determination of, 398.
 symptoms of aortic aneurysm, 928, 950, 951, 953.
 system, diseases of, 982-1176.
Response to treatment as a guide to cardiac prognosis, 758.
Rest, importance of, in treatment of heart conditions, 761, 823, 824, 876.
Retention of urine in typhus fever, 284.
Reticulocytes in blood in pernicious anæmia, 711, 713.
Retina, embolism of central artery of, 965.
Retinal changes in amaurotic family idiocy, 1478, 1479.
 hæmorrhages in anæmia gravis, 714.
 in arterial hypertrophy, 945.
 in infective endocarditis, 828.
 in leukæmia, 720.
 in nephritis, 1197, 1203, 1208.
 in pernicious anæmia, 711.
 in secondary contracted kidney, 1203, 1204.
 in subacute combined degeneration, 1621.
 pulsation in aortic incompetence, 842.
 tuberculoma, papilloedema in, 1410.
 veins in congenital heart disease, 898.
Retinitis, albuminuric, 945.
 in secondary contracted kidney, 1203.
 in uræmia, 1215.
Retinitis, diabetic, 411.
Retrobulbar neuritis, 411, 1372, 1373.
Retro-colic spasm, 1564.
 -pharyngeal abscess, 500.
 acute, 500.
 chronic, 500.
 in glandular fever, 291.
 in relation to lymphatism, 609.
Revaccination, 277.
Reversed rhythm, 742.
Rhagades in congenital syphilis, 204.
Rheumatic endocarditis, 295.
 fever, 292-301.
 aberrant types of, 295.
 ætiology of, 292-294.
 age-incidence of, 294.
 causal organisms of, 292-294.
 complications of, 295, 296.
 convalescence in, 296, 300.
 course of, 296.
 diagnosis of, 297, 298.
 drugs used for, 298-300.
 focal infections in, 292, 293, 301.
 in children, 296, 297.
 local treatment of, 300.
 preventive treatment of, 300, 301.
 prognosis in, 296.
 relation of purpura to, 728.
 seasonal incidence of, 294.
 streptococci in, 55, 292, 293.
 sweating in, 8, 294.
 symptoms of, 294, 295.
 treatment of, 298-301.
 gout. *See* Arthritis, non-specific infective.
 infection of heart in childhood, 819.
 nodules, 296, 297.
 state as decreased resistance to streptococci, 15.

values of foods, 435, 437.
- Vitamin A**, 432, 433.
effect of lack of, 432.
in relation to xerophthalmia, 432.
- B or B₁**, 432, 435, 436.
in relation to beriberi, 432.
- B₂ or PP**, 436.
in relation to pellagra, 432, 436.
- C**, 436-438.
in relation to scurvy, 432.
- D**, 433, 434.
artificial production of, 443.
in relation to rickets, 432.
relation of ergosterol to, 432.
- E**, 434, 435.
in relation to sterility, 432.
- Vitamins**, 431-438.
chemical characters of, 432.
discovery of, 431, 432.
- Vitamins**, fat-soluble, 432-435.
groups of, 432.
in relation to epidemic dropsy, 449.
relation of, to disease, 432.
sources of, 432, 433, 435, 436.
water-soluble, 435-438.
- Vitiligo**, 1361.
- Vocal cords**, abductor paralysis of, 1016, 1017.
epithelioma of, 1014.
paralysis of, 1016-1019.
recurrent paralysis of, 1016, 1017.
- fremitus**, 983.
- Voice**, change in, in paralysis agitans, 1524.
conduction, 985.
-production, faulty, 1002, 1007.
sounds, 985.
- Voluntary movement**, disorders impairing, 1472, 1473.
- Volvulus** as cause of acute intestinal obstruction, 604, 606, 607.
- Vomiting**, 522, 523.
aetiology of, 522, 523.
at onset in pneumonia, 1124.
central, 522.
cyclic, ketosis in, 404.
faecal, 605.
hysterical, 523, 534.
treatment of, 534, 535.
in achalasia of the cardia, 509.
in acute gastritis, 538.
in acute intestinal obstruction, 605.
in acute pancreatitis, 664.
in acute peritonitis, 679, 680.
in acute poliomyelitis, 143, 150.
in acute yellow atrophy, 627.
in Addison's disease, 454.
in alcoholic gastritis, 510, 511, 541.
in anæmic dyspepsia, 535.
in anoxæmia, 354.
in apoplexy, 1451.
in appendicitis, 609, 613.
in arsenical poisoning, 369.
in blackwater fever, 226.
in botulism, 396.
in caisson disease, 350, 351.
in cancer of the œsophagus, 514.
in cancer of the stomach, 553.
in cardiac failure, 754, 766, 768.
in cerebro-spinal fever, 154, 163, 168.
in cholecystitis, 653.
in cholera, 87, 88.
in chronic alcoholism, 365.
in chronic gastric ulcer, 545.
in congenital hypertrophy of the pylorus, 557.
in diphtheria, 93, 94, 96, 103.
in epilepsy, 1539.
in Henoch's purpura, 728.
in Hirschsprung's disease, 601.
in hour-glass stomach, 559.
in intracranial tumour, 1412.
in lead poisoning, 372.

- Vomiting** in lethargic encephalitis, 144.
 in Ménière's disease, 523, 1389.
 in œsophageal and pharyngeal diverticula, 511.
 in œsophagitis, 512.
 in paratyphoid fever, 78.
 in post-basic meningitis of infants, 167.
 in pregnancy, 523, 534.
 in pyloric obstruction, 556.
 in relapsing fever, 187, 188.
 in scarlet fever, 252, 255, 262, 263.
 in sea-sickness, 523.
 in small-pox, 267.
 in spirochaetosis ictero-hæmorrhagica, 185.
 in suppurative encephalitis, 1428.
 in suppurative pyelphlebitis, 651.
 in tuberculous meningitis, 1435.
 in typhoid, 66.
 in undulant fever, 174.
 in uræmia, 1215, 1216.
 in waterbrash, 510.
 in whooping-cough, 130, 131, 132.
 in yellow fever, 313.
 of pregnancy, pernicious, 534.
 post-anæsthetic, 523.
 reflex, 522, 523.
 toxæmic, 50, 163.
 toxic, 523.
 treatment of, 523.
- von Graefe's sign** in hyperthyroidism, 462.
- von Jaksch's disease.** See Anæmia pseudo-leukæmia infantum.
- Vulvar diphtheria**, 95.
- Vulvitis** in typhoid, 69.
- Waller's** capillary electrometer, 912.
- War conditions** in relation to acute suppurative bronchitis, 1036, 1037.
disease, ulcero-membranous stomatitis as a, 491.
 in relation to typhoid, 62.
- Warbles** in myiasis, 343.
- Wart**, post-mortem, 1336.
- Warts**, 1353, 1354.
 gonorrhæal, 1354.
- Wassermann reaction** as guide to treatment, 215-218.
 fallacies of a negative, 215.
 first appearance of positive, 195.
 hæmolytic as principle of, 22.
 in cerebro-spinal fluid, 1432.
 in diagnosis of syphilis, 195.
 in syphilis of heart and aorta, 890, 891, 892.
 in syphilis of the nervous system, 1483, 1484.
 in typhus fever, 282.
 in Vincent's angina, 498.
- Water** as vehicle of cholera infection, 88.
 of typhoid infection, 62.
 lead contamination of, 373, 374.
- Water poisoning**, 8.
 supply in relation to goitre and cretinism, 470, 472.
- Waterbrash**, 510, 511.
 ætiology of, 510.
 character of fluid in, 510.
 symptoms of, 510, 511.
- Water gas**, dangers of, 376.
- Water-pock.** See Chicken-pox.
- Watsonius watsoni**, 329.
- Waxy** discoloration of arteries. See Arterial infiltration.
- Weber's syndrome**, 1364, 1377.
 test for nerve deafness, 1387.
- Weed-killer**, arsenical, 368.
- Weil's disease**, 311.
 pathology of, 311.
 symptoms of, 311.
- Weil-Felix reaction**, 72.
 in typhus, 282.
- Werdnig-Hoffmann disease**, 1639-1641.
- Wernicke's aphasia**, 1462.
 hemianopic pupil phenomenon, 1379, 1401.
- West's** swab for detection of meningococcus in throat, 154.
- Weyl's test** for creatinin, 1178.
- Whip-worm**, the, 341.
- White** nervous matter prone to suffer in caisson disease, 348, 351.
- White-spot disease**, 1351.
- Whitfield's ointment** for ringworm, 1312.
- Whitlow**, diphtheric, 95.
- Whitlows** in syringomyelia, 1605.
- "Whoop"** of whooping-cough, the, 130, 131, 132.
- Whooping-cough**, 129-134.
 adenoids and, 134.
 ætiology of, 129, 130.
 age-incidence of, 129.
 bacteriology of, 129.
 complications in, 131, 132.
 course of, 131.
 diagnosis of, 132, 133.
 drugs used for, 133, 134.
 immunity after, 130.
 in relation to measles, 244.
 in the adult, 131.
 incubation period of, 130.
 infection of, 130.
 infectivity of, 129, 130.
 leucocytosis in, 131.
 mortality in, 133.
 prognosis in, 133.
 quarantine in, 134.
 radio-therapy in, 134.
 seasonal incidence of, 129.
 symptoms of, 130, 131.
 treatment of, 133, 134.
 tuberculosis and, 132, 133.
 vaccine treatment of, 134.
- Widal test**, 70.
- Wills**, the circle of, 1442.

- Willis**, the circle of, in relation to aneurysm. 1444.
- Winckel's disease**, 621, 730, 731.
- "Winged scapula,"** 1642.
- Wolfez, maladie de**, 1061.
- Wolff's** bottles for use after pleural effusion, 1148.
- Wolves**, rabid, and rabies, 307.
- Wood's glass screen** for diagnosis of ring-worm, 1309.
- Woolner's tip**, 425.
- Wool-sorter's disease.** *See* Anthrax.
- Word-blindness**, 1460.
in lesions of occipital lobe, 1401.
in lesions of temporal lobe, 1402.
pure, 1460, 1463.
lesions producing, 1460.
with agraphia, 1461.
- Word-deafness**, 1461, 1463.
in lesions of temporal lobe, 1402.
- Wounds**, diphtheria of, 95.
in relation to septicaemia, 51.
scarlet fever after, 256, 257.
- Wrist-drop**, in lead neuritis, 375, 1661.
- Writer's cramp**, 1571, 1572.
- Writing**, executive areas for, 1464.
- Xanthelasma**, 616.
- Xanthochromia** (of cerebro-spinal fluid). 1431, 1595, 1613.
- Xanthoma**, 1340, 1341.
diabeticorum, 1341.
multiple, 616.
planum, 1341.
symptoms of, 1341.
treatment of, 1341.
tuberosum, 1341.
varieties of, 1340.
- Xanthopsia**, 617, 618.
- Xenopsylla cheopis**, the rat-flea of plague, 170.
- Xerodermia**, 1274, 1275.
aetiology and pathology of, 1274.
pigmentosa, 1362.
symptoms of, 1274, 1275.
treatment of, 1275.
- Xerophthalmia**, vitamin A in relation to, 432, 433.
- Xerosis bacillus**, 91.
- Xerostomia**, 492, 493.
aetiology of, 492, 493.
in relation to digestion, 493.
symptoms of, 493.
treatment of, 493.
- X-ray dermatitis**, 1286.
- X-ray examination**, importance of, in thoracic aneurysm, 953, 954.
in diagnosis of peritoneal adhesions, 685, 686.
of intestinal functions, 560, 561, 562.
- treatment**, of acne vulgaris, 1306.
of hyperthyroidism, 465.
of leukemia, 722.
of ringworm of scalp, 1310.
of splenic anaemia, 739.
- Yatren** in amoebic dysentery, 239.
- Yaws**, 218-220.
aetiology of, 218, 219.
complications of, 219.
course of, 219.
diagnosis of, 219.
Fijian variety of, 219.
infection in, 219.
pathology of, 219.
prognosis of, 219.
symptoms of, 219.
treatment of, 219, 220.
- Yeast** in pellagra, 454.
vitamin content of, 436.
- Yeasts**, stomach, 518.
- Yellow fever**, 312-215.
aetiology of, 312, 313.
complications and sequelae of, 314.
diagnosis of, 314.
endemic haunts of, 312.
larval form of, 313.
malignant, 314.
Mediterranean, 311.
mild, 313.
mortality in, 314.
negro resistant to, 14, 312.
pathology of, 313.
prognosis of, 314.
severe, 313, 314.
symptoms of, 313, 314.
treatment of, 314, 315.
types of, 313.
vaccine, 515.
- Yeo, Dr. Burney**, his antiseptic treatment of typhoid, 76.
- Yersin's** anti-plague serum, 172.
- Zenker's** degeneration of muscle, 1261.
vitreous degeneration of muscle, in typhoid, 63.
- Ziehl-Neelsen** staining of tuberculous sputa, 113.
- Zymogens of pancreas**, 664.
